The electronics revolution, which began in the 1960s, drove the miniaturization of radio, television, hard disk drives, camcorders, personal digital assistants, etc., to the point where miniaturization now appears commonplace. More recent is the miniaturization of components that are not based on integrated circuits in hardware such as physical, chemical, and biological sensors and analytical instruments. Progress in this newer area is derived from mature, traditional manufacturing technologies such as mechanical precision machining, as well as from lithography-based nontraditional microelectromechanical system (MEMS) and nanoelectromechanical system (NEMS) techniques. The encroaching limits of our planet's resources and the continuing deterioration of the environment are adding urgency to this trend of scaling things down in size.

In Table 7.1 we list sound reasons for miniaturizing systems, actuators, power sources, sensors, and components. In some cases, the reason is favorable scaling—for example, smaller devices tend to be faster and consume less power. Scaling may also disfavor miniaturization, as often happens with actuators and power sources; smaller actuators exert less force, and smaller power sources harness less power.

In this chapter, we analyze scaling laws and the size regimes where macrotheories start requiring corrections. We aspire to elucidate the unexpected behavior of some of these micromachines and to better understand why, in some cases, it makes sense to miniaturize a device for reasons beyond economics, volume, and weight. Following some comments about human microintuition, we introduce the concepts of

Table 7.1 Motivations to Miniaturize Systems, Actuators, Power Sources, Sensors, and Components

Miniaturization Attributes	Motivations
Low energy* and little material consumed	There are limited resources on planet Earth
Arrays of sensors	Redundancy, wider dynamic range, and increased selectivity through pattern recognition
Small	Smaller is lower in cost, minimal invasive
Favorable scaling laws (in some cases)	Forces that scale with a low power become more prominent in the microdomain; if these are positive attributes then miniaturization is favorable, e.g., surface tension becomes more important than gravity in narrower capillaries
Batch and beyond batch techniques (roll-to-roll manufacturing)	Lowers cost
Disposable	Helps avoid contamination
Breakdown of macrolaws in physics and chemistry	New physics and chemistry might be developed
Increased sensitivity (in some cases)	Nonlinear effects can increase a sensor's sensitivity, e.g., amperometric sensors
Smaller building blocks	The smaller the building blocks, the more sophisticated a system that can be built

* There is a significant debate about this point. If the total environmental "cost" for a product is considered, miniaturized products might be worse for the planet. It is similar to the debate about hybrid cars: they save on gas, but the environmental impacts of producing the batteries are often ignored.

isometry, allometry, and dimensional analysis—mathematical techniques that help us predict the influence of downscaling more reliably. The lessons learned are then applied to some scaling applications in both natural and human-made "machines." We end the chapter by introducing some examples where scaling laws break down and where noncontinuum models must be invoked. In a continuum, all quantities are defined everywhere and vary continuously from point to point; in a noncontinuum this continuity breaks down.

Microintuition

As children, we learned to deal with everyday objects having size and scale dimensions that are naturally "sized up" by our senses, and we were mystified and enthralled by anything much larger (Gulliver) or smaller (Tom Thumb) (see Figure 7.1). It is indeed much more difficult to get a feel for or understand the consequences of dimensions of physical systems many orders of magnitude larger or smaller than what we commonly experience. Of all our senses, vision informs our mind the most. The unaided eyes generally give us the ability to discern things as small in size as an ant's eye or the point of a pin (approximate size, 50 μm). However, telescopes and microscopes continue to improve and greatly extend our sensory capabilities in our quest to understand and utilize our material world better, including systems spanning extreme length scales from the astronomical to the atomic. These new sets of eyes have greatly assisted us in assessing the size and scale of diverse natural and artificial material systems. Today telescopes allow us to see galaxies 13 billion light-years away (10^{25} m), and microscopes allow us to see even single atoms (about 10^{-10} m)!

Q: Gulliver was twelve times as tall as the Lilliputians. How much should they feed him? Could it be twelve times their own food ration? Hint: A person's food needs are related to his or her mass (volume), which depends on the cube of the linear dimension.

A: Let l_G and V_G denote Gulliver's linear and volume dimensions. Let l_L and V_L denote a Lilliputian's linear and volume dimensions. Gulliver is twelve times as tall as the Lilliputians, or

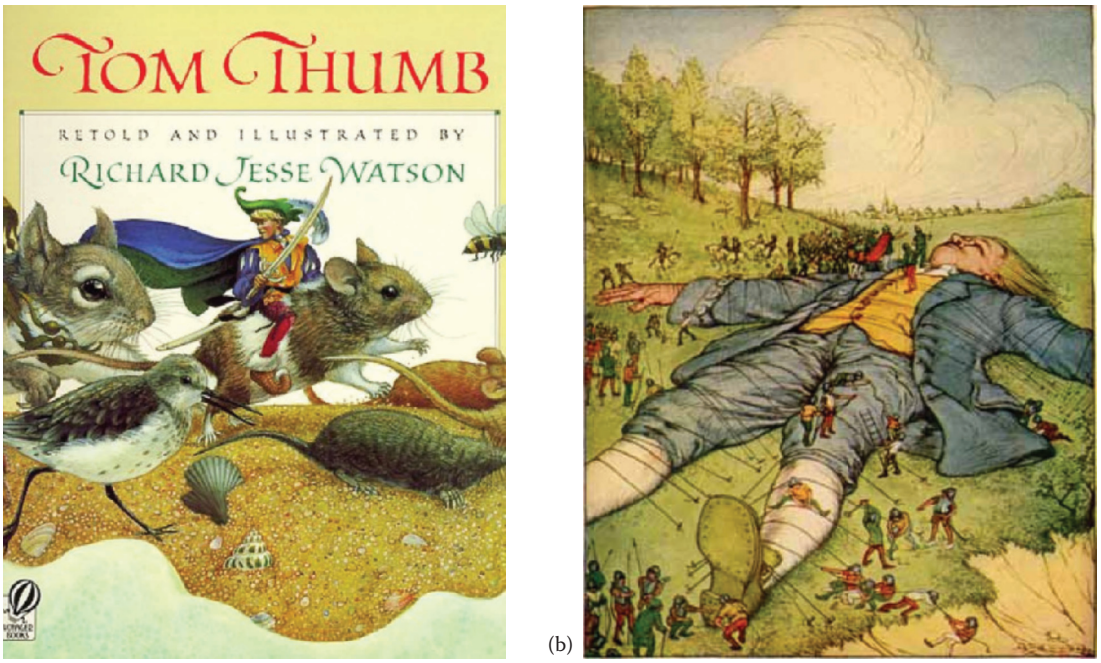

FIGURE 7.1 *Tom Thumb* originally by the Brothers Grimm (a) and *Gulliver's Travels* by Jonathan Swift (b).

$l_G = 12\ l_L$. Then, $V_G \propto (l_G)^3$ and $V_L \propto (l_L)^3$, so $V_G/V_L = (l_G)^3/(l_L)^3 = (12\ l_L)^3/(l_L)^3 = 12^3 = 1728$. Gulliver needs to be fed 1728 times as much food each day as a Lilliputian. This may be the real reason Gulliver was driven out of Lilliput. (Courtesy of W. Wilson, University of Central Oklahoma).

Humans are accustomed to thinking in distances and sizes—even microsizes have become quite intuitive, more so than microtimes. To accommodate the human inability to comprehend minute segments of time, Isaac Asimov introduced a measure based on the speed of light. Asimov's *light-meter* is the time required for light (in a vacuum) to cover the distance of a meter. An illustrative case is the half-life of radioactive particles. Saying that the half-life of a first particle is of the order of a hundredth of a millionth of a second and that of a second particle is of a thousandth of a trillionth of a second makes little impression. On the other hand, saying that the half-life of one type of particle is of the order of a light-meter and that of the other is of a tenth of a light-micrometer is more effective. We find linear extrapolation of length easy but are quickly at a loss when considering the implications that shrinking of time segments has or shrinking of surface-to-volume ratios on the relative strength of external forces working on miniaturized structures. In dealing with very small devices, our *microintuition*—as Bill Trimmer calls it—is often misleading (see also http://home.earthlink.net/~trimmerw/mems/tutorials.html).[1]

The effect of downscaling, especially into the nanodomain, is indeed not well understood and leads to some very surprising and sometimes counterintuitive results. For example, scaling shows that NEMS devices feature fundamental frequencies in the microwave range, active masses in the femtogram range, mechanical quality factors (Qs) in the tens of thousands, force sensitivities in the attonewton level, mass sensitivities at the level of individual atoms, and heat capacities far below yoctocalories. NEMS will make for electromechanical components with response times and operating frequencies that are as fast as most of today's electron devices. We now introduce a rigid mathematical formulation for scaling of a system, illustrating the newly gained insights with observations from nature. Our aim is to develop a systematic approach about the likely behavior of downsized systems so we do not need to rely on microintuition alone.

In Figure 7.2 we illustrate some known and not-so-well-known objects and their respective sizes,

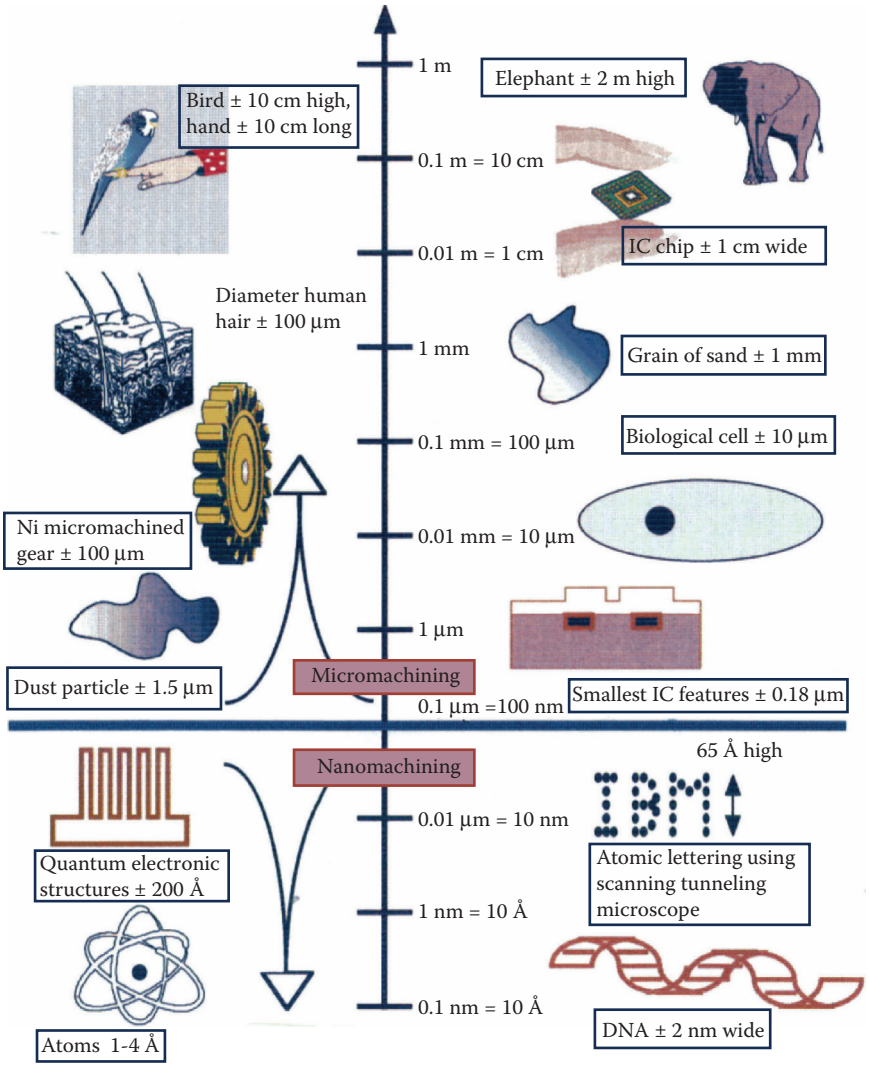

FIGURE 7.2 Various objects and their linear size.

including MEMS and NEMS, organized in powers of ten.

Mathematical Approach to Scaling

Introduction

In his book *On Growth and Form* (first published in 1917), D'Arcy Wentworth Thompson explains the profound effects of scaling in nature. Thompson (1860–1948) was a mathematically trained zoologist who pioneered the field we call *biomathematics* today (scaling laws in nature are a subset of biomathematics). He recognized many strong mathematical patterns in nature (spiral seashells, zebra stripes, etc.) and tried to find an explanation for the physical principles behind them. His book is the work of a true maverick and still inspires those interested in a mathematical understanding of biology. For a more recent account on growth and form in nature, including a more detailed mathematical treatment of scaling in animals, we refer to Knut Schmidt-Nielsen.[2] A popularizing and exquisitely illustrated work on the same topic is Thomas McMahon and John Bonner's *On Size and Life*.[3]

Similarity or Isometry, Allometry, Fractals, and Dimensional Analysis

A scaling law describes the variation of physical quantities with the size of the system. To understand scaling, it is essential to develop a notion for the concept of similarity or isometry. The idea is familiar from geometry: for example, two triangles are

said to be similar or isometric if all of their angles are equal, even if the sides of the two triangles are of different lengths. The two triangles have the same shape; the larger one is simply a scaled up version of the smaller one. This notion can be generalized to include complex organisms or human-made artifacts such as engines, boats, and aircraft.

In the most general case, to compare the relative sizes of two structures, x and y, one may write:

$$y = bx^a \qquad (7.1)$$

where a and b are constants. If the exponent a equals zero, then y and x are independent. This holds, for example, for the size of a cell (y) as a function of animal size (x); the cell diameter (b) is independent of animal size (about 10 µm, see Chapter 2). In case of a linear relationship between y and x, a equals 1, and x and y are said to be isometric or exhibit geometric similarity—the proportions of the structures that are being compared do not change with a change in size. Isometric change occurs when each dimension of a structure is scaled up or down regardless of the disproportionate change in such parameters as surface area and volume. If x doubles in length, then so does y. The proportions remain constant and do not change with a change in size. Besides the aforementioned triangles, the nine planets and the ten nested Russian dolls shown above are all simple examples of isometry, in which the proportions do not change with size.

From the rules of isometry, we expect that for geometrically similar animals of the same mass density, the body mass, m, will be proportional to the cube of the body length, l^3, and that the area, S, will be proportional to l^2. In a number of species, body surface areas proportional to the 2/3 power of body mass are just what is found. This is illustrated in Figure 7.3 where we have plotted the surface area versus body mass for a species of salamander in a log-log plot. To elucidate the plot in Figure 7.3[4], we first rewrite Equation 7.1 in its logarithmic form and obtain the following.

$$\log y = \log b + a \log x \qquad (7.2)$$

In the example case the slope a equals 2/3, or 0.67, and fits the isometric prediction exactly. The value of b is of significance as well; it fixes the value for y when x is equal to 1. Comparisons made over a limited size range, say within a given species of plants or animals and types of bridges or boats, are often isometric.

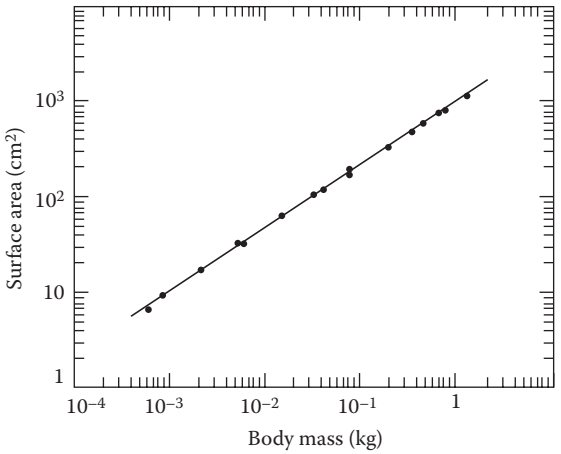

FIGURE 7.3 Surface area versus body mass for a species of salamander, the dwarf siren (*Pseudobranchus striatus*). The surface area, *S*, is proportional to the body mass, *m*, raised to the 0.67 power.

When, on the other hand, comparing animals, plants, engines, or boats of greatly differing size, proportions do often change with size, and one speaks about allometry. Allometric change occurs when the proportions of an organism adjust to the different rates at which surface area, volume, and other physical parameters change with differing sizes. It is sometimes referred to as *differential scaling*. Perhaps the most famous allometric relationship pertains to the metabolic machinery of animals. In 1932, Max Kleiber, an American veterinary scientist, found that the basal metabolic rate (the rate at which the body generates heat when the organism is at rest), as measured by the rate of oxygen consumption or heat production, is proportional to $m^{0.75}$ over a very wide range of animals. In Figure 7.4, we show what has become known as *Kleiber's law*, which says that the metabolic rate for a wide range of different species is proportional to $m^{0.75}$ (the broken line with a slope of 0.67 = 2/3 has been added for comparison). This law has been shown to be approximately true over twenty orders of magnitude (from single cells to elephants). There are a large variety of other phenomena that change with body size according to quarter-power law scaling. For example, a cat,

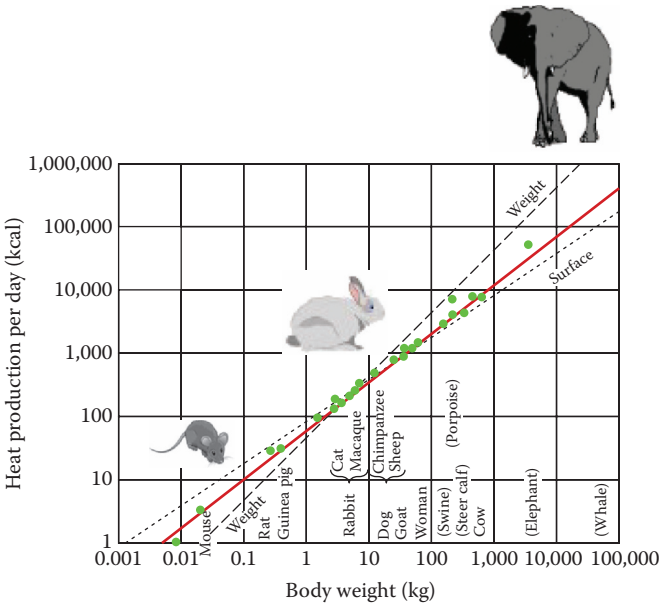

FIGURE 7.4 A log-log plot of metabolic heat production against body weight, taken from Kleiber's 1947 article. It is clear that most points (green) closely fit the red line with a slope of three quarters, rather than the weight line (slope of 1) or the surface line (slope of two thirds). Note that although the differences between the lines seem small, this is a log-log plot, so the deviations are actually vast.

100 times the weight of a mouse lives about $100^{1/4}$, or about three times, as long as a mouse, and heartbeat scales as $m^{-1/4}$, so the cat's heart beats one-third as fast as a mouse's.

The reason for Kleiber's allometric relation has eluded scientists for a long time. For metabolism, molecules inside and outside cells, such as carbohydrates, enzymes, hormones, nucleic acids, must interact and react with each other. If a cell and its organelles were not limited to a size of only a few micrometers in diameter, then it would be difficult for the various molecules to diffuse and come in contact within a reasonable amount of time. The small cell size maximizes surface-to-volume ratio (S/V), allowing for the most efficient metabolism. In larger organisms, individual cells are accessed via distribution networks: in plants, a vascular system of xylem and phloem carries water and nutrients to and from the different parts of the organism, and in animals, the circulatory system of veins plays the same role. If S/V was the main factor involved in controlling metabolic rate, that rate would be expected to scale to the body mass of an organism to the two-thirds power. Plotting the basal rate of oxygen consumption rate within a given species is indeed often found to be proportional to $m^{0.67}$. On this basis, for a cat, 100 times more massive than a mouse, we expect to have a basal metabolism of $100^{0.67}$, or about 21.5 times that of the mouse. But Kleiber's law, which applies when one looks across different species and over a wide range of sizes, means that a cat's metabolic rate is not 21.5 times greater than a mouse's, but 31.6 times. One of the more inspiring explanations for Kleiber's law came from ecologists Enquist and Brown and physicist West in 1997. These authors explain that the generic principle underlying Kleiber's law is that nutrient supply networks in animals and plants form a branching fractal network* to reach all cells in an organism. They showed that they could derive Kleiber's 3/4-power scaling law by invoking these fractal networks. In their analysis, then, the metabolism scales as the dimension of the circulatory system, which is after all what delivers the energy being metabolized.† Allometric changes in proportions are often compensations for competing requirements of surface area, cross-sectional area, and volume. In this case, nature evidently evolved a method to overcome the natural limitation of simple geometric scaling by developing these more efficient fractal-like webs to connect all the similarly sized cells within an organism. Fractals are an optimal geometry for minimizing the work lost due to the transfer network while maximizing the effective surface area (see Figure 7.5, with a tree as an example of a fractal). We believe that this insight might be of great value in human engineering endeavors where reagents and reaction products must be distributed with maximum efficiency throughout the bulk of a device, be it a fuel cell, a battery or a sensor. In electrochemical systems, it is advantageous to have a large S/V when there is the need to transfer the signal or power effectively to an electrical network.

* In a fractal network, each tiny part is a replica of the whole. In the current context, think about blood capillaries in our bodies and their botanical equivalent in trees: a silhouette of the human circulatory system and of roots and branches of a tree actually look remarkably similar.

† The theory is not without is detractors; Dodds at MIT, for example, disputes the very existence of the 3/4 law.[5] A 2005 paper by West and coworkers seems to vindicate this team's work.[6]

FIGURE 7.5 A tree as an example of a fractal.

We will demonstrate in Chapter 9, this volume, in the section on miniaturizing power sources, that fractal geometries for the electrodes might be the best solution for maximizing the current while minimizing the internal resistance.

Having reviewed the basics of isometry and allometry, we now introduce the concept of dimensional analysis, one of the simplest yet most powerful tools in a physicist's bag of tricks. Dimensional analysis is important when modeling physical phenomena, for instance, predicting the performance of a large plane on the basis of observing a small-scale model in a wind tunnel or the reverse—more relevant in miniaturization science—predicting the behavior of a miniaturized machine on the basis of the performance of a larger model. Besides predicting the behavior in scale-up or scale-down experiments, dimensional analysis is of use in the deduction of physics laws (physics demands dimensional consistency in equations), reduction of number of variables by introducing dimensionless groups and order of magnitude analysis (which terms dominate in an equation). Langhaar described dimensional analysis as "a method by which we deduce information about a phenomenon from the single premise that the phenomenon can be described by a dimensionally correct equation among certain variables."[7]

The dimensional specification for a physical variable is its *dimensional formula*. The dimensional formula shows the fundamental or base quantities (denoted by capital letters) raised to the appropriate powers and enclosed in brackets. There are seven fundamental base quantities in these dimensional formulas: time, length, mass, electrical current, temperature, amount of a substance in moles, and luminous intensity. All other quantities, dimensions, and units are known as *derived quantities*. For example, the dimensional formula for acceleration, a, is $[LT^{-2}]$. In the simplest use, dimensional analysis helps one decide whether an equation is correct as the dimensions on both sides of the equality sign must be the same and one can figure out the dimensions of a particular variable if the others are known.

In a more advanced use of dimensional analysis, the object is to substitute a set of dimensionless numbers for the dimensional physical variables that describe the problem—pressure, velocity, density, and so on. As the dimensionless numbers are products or ratios of the physical variables, this process always succeeds in reducing the number of variables in the problem. This reduction in the number of variables is a very worthwhile exercise since it frequently saves a great deal of experimental effort.

We introduce first the two most important theorems of dimensional analysis and follow that by listing a number of detailed steps to carry out a typical dimensional analysis using the exponent method or Buckingham method. Finally, we present a couple of examples and an exercise that will turn out to be of use later on in this chapter.

First Theorem

The dimensional homogeneity theorem states that any physical quantity is dimensionally a power law monomial: $[\text{Any Physical Quantity}] = [M^a L^b T^c]$.

Second Theorem

The Buckingham Π theorem (Pi theorem) states that if a system has k physical quantities of relevance that depend on r independent dimensions, then there are a total of $k - r$ mutually independent dimensionless groups $\pi_1, \pi_2, \ldots, \pi_{k-r}$. The dimensionless groups are called *pi-terms*. The behavior of the system is then describable by a dimensionless equation $F(\pi_1, \pi_2, \ldots, \pi_{k-r}) = 0$. The number of pi-terms is thus fewer than the original number of variables by r.

In practice, one proceeds as follows:

1. Make an informed guess about which parameters (variables), k, are likely to be important

in the phenomenon under scrutiny. These are typically all variables required to describe the problem geometrically (e.g., diameter, D), materials properties [e.g., fluid properties (ρ,μ)], physical constants (e.g., gravity, g—would things work differently on the moon?), and external effects (dp/dx, a pressure differential).
2. Express each variable in terms of its fundamental quantities (dimensions), [M], [L], [T], etc.
3. Determine the required number of dimensionless parameters ($k - r$).
4. Select a number of repeating variables equal to the number of dimensions (= r). All fundamental quantities must be included in this set, and each repeating variable must be dimensionless independent of the others.
5. Form a dimensionless parameter π by multiplying one of the nonrepeating variables by the product of the repeating variables, each raised to an unknown exponent.
6. Solve for the unknown exponents.
7. Repeat this process for each nonrepeating variable.
8. Express results as a relationship among the dimensionless parameters: $F(\pi_1, \pi_2, \pi_3, \ldots) = 0$.

Example 7.1

We apply the Buckingham method now to some example problems, starting with a simple one. Say you want to find out the drag force F_D on a body immersed in a flowing fluid (say a fish or a submarine moving underwater—let's call it a swimmer). The drag force F_D is the force opposing the object's velocity and will depend on the following:

$$F_D = f(l, v, \rho, \mu) \tag{7.3}$$

where k = 5 (number of variables/parameters) and r = 3 number of dimensions (L, T, and M).

Thus, the number of dimensionless numbers is expected to be 5 – 3 = 2. This is summarized in Table 7.2.

Select "repeating" variables: l, v, and ρ. Combine these with the rest of the variables: μ and F_D. So the first pi-term becomes $\pi_1 = \mu(l^a v^b \rho^c)$.

Table 7.2 There Are Five Parameters or Variables (k) and Three Fundamental Quantities

F_D	l	v	ρ	μ
MLT^{-2}	L	LT^{-1}	ML^{-3}	$ML^{-1}T^{-1}$

To calculate the exponents, one writes the following equation:

$$\pi_1 = \mu(l^a v^b \rho^c) \tag{7.4}$$

and since this combination is supposed to be dimensionless:

$$M^0L^0T^0 = (ML^{-1}T^{-1})(L)^a(LT^{-1})^b(ML^{-3})^c$$

$$M: 0 = 1 + c \rightarrow c = -1$$

$$L: 0 = -1 + a + b - 3c \rightarrow a = -1$$

$$T: 0 = -1 - b \rightarrow b = -1$$

The first π term is thus as follows:

$$\pi_1 = \mu/lv\rho,\ \pi_1 = 1/\text{Reynolds number (1/Re)} \tag{7.5}$$

usually written as follows:

$$Re = \rho vl/\mu \tag{6.71}$$

The Reynolds number, familiar from Volume I, Chapter 6, appears in a large number of fluid flow problems. It is the ratio of inertial forces over viscous forces. A more complete discussion of the Reynolds number is given in Volume I, Chapter 6, on fluidics. A list of other common dimensionless groups is represented in Appendix 7A. The second dimensionless group (pi-term) should be chosen in such a way that it is certain to be independent of the first pi-term. One way to do that is to make sure that at least one physical parameter that was present in the first group is missing from the second and vice versa. In the example case, we replace the viscosity μ by the drag force F_D, as follows:

$$\pi_2 = F_D(\rho^d l^e v^f) \tag{7.6}$$

$$M^0L^0T^0 = (MLT^{-2})(ML^{-3})^d(L)^e(LT^{-1})^f$$

$$M: 0 = 1 + d \rightarrow d = -1$$

$$L: 0 = 1 - 3d + e + f \rightarrow e = -2$$

$$T: 0 = -2 - f \rightarrow f = -2$$

This way we obtain a second dimensionless group, given as follows.

$$\pi_2 = F_D/\rho\, l^2 v^2 \tag{7.7}$$

This second group, $F_D/\rho\, l^2 v^2$, may be considered a dimensionless drag force. Using A as the wetted surface of the submerged swimmer, this dimensionless group may be rewritten as the drag coefficient C_D. Since $\pi_2 = f(\pi_1)$ we can also write the following.

$$C_D = F_D/\rho l^2 v^2 = f(\text{Re}) \tag{7.8}$$

For a given Reynolds number, the best design for a race car, submarine, or airplane is the one that minimizes drag coefficient C_D (see below under "Scaling in Flying").

Example 7.2

In a second example, we apply dimensional analysis to the drag force on a rough sphere in a flowing solution. Drag force on a rough sphere (with diameter D and roughness k) is a function of D, ρ, μ, v, and k. The relative roughness of the sphere is given as k/D:

$$k = 6 \text{ (number of variables/parameters)}$$

$$r = 3 \text{ number of dimensions } (L, T, \text{ and } M)$$

Thus, the number of dimensionless numbers is expected to be $6 - 3 = 3$. This is summarized in Table 7.3.

Select "repeating" variables: D, v, and ρ. Combine these with the rest of the variables: F_D, μ, and k. So the first pi-term is given as follows:

$$\pi_1 = \mu(D^a v^b \rho^c) \tag{7.9}$$

and since this combination is dimensionless:

$$M^0L^0T^0 = (ML^{-1}T^{-1})(L)^a(LT^{-1})^b(ML^{-3})^c$$

$$M: 0 = 1 + c \rightarrow c = -1$$

Table 7.3 There Are Six Parameters or Variables (k) and Three Fundamental Quantities

F_D	D	v	k	ρ	μ
MLT^{-2}	L	LT^{-1}	L	ML^{-3}	$ML^{-1}T^{-1}$

$$L: 0 = -1 + a + b - 3c \rightarrow a = -1$$

$$T: 0 = -1 - b \rightarrow b = -1$$

we again obtain $\pi_1 = \mu/lv\rho$, $\pi_1 = 1/\text{Reynolds number}$, abbreviated as $\text{Re} = \rho vl/\eta$ (Volume I, Equation 6.71). For the second dimensionless group we choose the repeating variables D, v, and ρ and combine those with the nonrepeating variables F_D, μ, and k.

$$\pi_2 = k(D^a v^b \rho^c) \tag{7.10}$$

$$M^0L^0T^0 = (L)(L)^a(LT^{-1})^b(ML^{-3})^c$$

$$M: 0 = c \rightarrow c = 0$$

$$L: 0 = 1 + a + b - 3c \rightarrow a = -1$$

$$T: 0 = -b \rightarrow b = 0$$

$$\pi_2 \equiv k/D \tag{7.11}$$

For the third pi-term, we write a dimensionless group as follows:

$$\pi_3 = F_D(D^a v^b \rho^c) \tag{7.12}$$

$$M^0L^0T^0 = (MLT^{-2})(L)^a(LT^{-1})^b(ML^{-3})^c$$

$$M: 0 = c + 1 \rightarrow c = -1$$

$$L: 0 = 1 + a + b - 3c \rightarrow a = -2$$

$$T: 0 = -2 - b \rightarrow b = -2$$

$$\pi_3 \equiv F_D/D^2 v^2 \rho \tag{7.13}$$

And since $\pi_3 \equiv f(\pi_2, \pi_1)$, we can also write the following equation:

$$F_D/D^2 v^2 \rho = f(\rho vl/\mu, k/d) \tag{7.14}$$

We encountered this expression when discussing the friction factor for pipe flow in Volume I, Chapter 6 (see Volume I, Equation 6.73). With the math introduced so far, we can express similitude or similarity a bit better now than the way we represented it in Equation 7.1. As we noted before, similarity is very important to be able to predict the behavior of a model with respect to the real life object. In miniaturization science the model is usually very large compared with the actual prototype device. Suppose the physical problem described in terms of dimensionless parameters is given as $\pi_1 = f(\pi_2, \pi_3, \ldots, \pi_n)$; applied

to the prototype, this transforms into $\pi_{1p} = f(\pi_{2p},\pi_{3p},\ldots,\pi_{np})$, and for the model of the prototype it reads as $\pi_{1m} = f(\pi_{2m},\pi_{3m},\ldots,\pi_{nm})$. The similarity requirements for modeling then become the following:

$$\begin{aligned} \pi_{2m} &\equiv \pi_{2p} \\ \pi_{3m} &\equiv \pi_{3p} \\ &\ldots\ldots \\ \pi_{nm} &\equiv \pi_{np} \\ \Rightarrow \text{then } \pi_{1m} &\equiv \pi_{1p} \end{aligned} \qquad (7.15)$$

In other words, under these conditions the dependent variables for prototype and model will be the same. Similarity comes in different flavors. There is, first of all, geometric similarity (scale factor); i.e., the ratio of lengths in the scale model compared with the full scale case is constant (all angles are identical). Then there is kinematic similarity, in which the ratios of velocity, acceleration, and flow rate between the scale model and the full scale are constant (time-dependent behavior of the model). Finally, there is dynamic similarity, where the ratios of forces on scale model and full-scale case are constant.

To illustrate these distinctive similarities, consider predicting the drag on a thin rectangular plate ($w \times h$) from a model placed normal to a flow. The drag function in this case will be $F_D = f(w, h, \mu, \rho, \text{and } v)$. Dimensional analysis shows that $\pi_1 = f(\pi_2, \pi_3)$, and this applies to both model and prototype. Working out the problem leads to an expression very similar to the one in Equation 7.14 (drag on rough sphere instead of on a plate):

$$F_D/ w^2v^2\rho = f(\rho vl/\mu, w/h) \qquad (7.16)$$

We can design a model to predict the drag on the prototype, since the drag on the model will be $F_{Dm}/w_m^2v_m^2\rho_m = f(\rho_m v_m l_m/\mu_m, w_m/h_m)$ as $\pi_{1m} = f(\pi_{2m}, \pi_{3m})$, and for the prototype we will have $F_{Dp}/w_p^2v_p^2\rho_p = f(\rho_p v_p l_p/\mu_p, w_p/h_p)$ as $\pi_{1p} = f(\pi_{2p}, \pi_{3p})$. The geometric similarity conditions give us the size of the model, with $\pi_{2m} \equiv \pi_{2p}$, $w_m/h_m = w_p/h_p$. For the kinematic similarity, we look at the π_3 terms ($\pi_{3m} = \pi_{3p}$), namely $\rho_m v_m l_m/\mu_m = \rho_p v_p l_p/\mu_p$, or the velocity of the model is as follows:

$$v_m = \frac{\mu_m \rho_p l_p}{\mu_p \rho_m l_m} v_p \qquad (7.17)$$

For the dynamic similarity—the drag force—on the prototype, we calculate from $\pi_{1m} \equiv \pi_{1p}$.

$$F_{Dp} = \left(\frac{w_p}{w_m}\right)^2 \frac{\rho_p}{\rho_m} \left(\frac{v_p}{v_m}\right)^2 F_{Dm} \qquad (7.18)$$

Exercise 7.1

A model of a submarine is 1/20th scale and is moving in fresh water (20°C) at a speed of 2 m/s. Find the speed of the model and the ratio of the drag force on the model to that of the real submarine moving in seawater. The density of seawater ρ is 1015 kg/m^3, and $\nu = \mu/\rho = 1.4 \times 10^{-6}$ m^2/s.

From the Reynolds number ($Re_m = Re_p$), we can calculate the speed of the model in fresh water (kinematic similarity).

$$\frac{v_m l_m}{\nu_m} = \frac{v_p l_p}{\nu_p} \text{ or } v_m = \frac{\nu_m l_p}{\nu_p l_m} v_p = \frac{1}{1.4} \times \frac{20}{1} \times 2\text{m/s}$$

$$v_m = 28.6 \text{ m/s}$$

To calculate the ratio of the drag forces we rely on the dynamic similarity.

$$\frac{F_m}{\rho_m v_m^2 l_m^2} = \frac{F_p}{\rho_p v_p^2 l_p^2} \text{ or}$$

$$\frac{F_m}{F_p} = \frac{\rho_m v_m^2 l_m^2}{\rho_p v_p^2 l_p^2} = \frac{1000}{1015}\left(\frac{28.6}{2}\right)^2\left(\frac{1}{20}\right)^2$$

$$\frac{F_m}{F_p} = 0.504$$

Trimmer's Vertical Bracket Notation

From the preceding section, we appreciate that as the scale of structures decreases, so does the importance of phenomena that vary with the largest power of the linear dimension l. Phenomena that are more weakly dependent on size dominate in small dimensions: electrostatics (l^2), friction (l^2), surface tension (l), diffusion ($l^{1/2}$), and van der Waals forces ($l^{1/4}$). High-power forces include gravity (l^3) (the mass of a system, m, scales as l^3), inertia (l^3), magnetism (l^2, l^3, or l^4, depending on the exact configuration), flow (l^4), and thermal emission

(l^2 to l^4). Scaling laws may be positive or negative order. Positive-order laws imply that the property grows with increasing scale, and negative-order laws imply that the property grows with decreasing scale. A zero-order law implies that a property is invariant with scale. In other words, positive orders affect large objects and negative orders small objects.

Trimmer introduced an elegant method to express different scaling laws by using a vertical bracket notation. For different possible forces, he writes:

$$\begin{bmatrix} l^1 \\ l^2 \\ l^3 \\ . \\ . \\ l^n \end{bmatrix} = F \tag{7.19}$$

The top element in this notation refers to the case where the force scales as l^1. The next one down refers to a case where the force scales as l^2, etc. If the system becomes one-tenth its original size, all the dimensions decrease by a tenth. The mass of a system, m, scales as l^3, and as systems become smaller, the scaling of the force also determines the acceleration a, transit time t, and the amount of power per unit volume (PV^{-1}). For a generalized case with a force F scaling as l^F, we obtain

$$a = \frac{F}{m} = \left[l^F\right]\left[l^{-3}\right] \tag{7.20}$$

for acceleration a,

$$t = \sqrt{\frac{2xm}{F}} = \left(\left[l^1\right]\left[l^3\right]\left[l^{-F}\right]\right)^{\frac{1}{2}} \tag{7.21}$$

for transit time t, with x = distance, and

$$\frac{P}{V} = \frac{Fx}{tV} \tag{7.22}$$

for power per unit volume. Applying Equation 7.20 to Equation 7.22 to calculate a, t, and PV^{-1} for forces scaling with varying power of the linear dimension, we obtain the following:

$$\begin{bmatrix} l^1 \\ l^2 \\ l^3 \\ . \\ . \\ l^n \end{bmatrix} = F \rightarrow \begin{bmatrix} l^{-2} \\ l^{-1} \\ l^0 \\ . \\ . \\ l^{n-3} \end{bmatrix} = a \rightarrow \begin{bmatrix} l^{1.5} \\ l^1 \\ l^{0.5} \\ . \\ . \\ l^{\sqrt{4-n}} \end{bmatrix} = t \rightarrow \begin{bmatrix} l^{-2.5} \\ l^{-1} \\ l^{0.5} \\ . \\ . \\ l^{n-2-\sqrt{4-n}} \end{bmatrix} = \frac{P}{V} \tag{7.23}$$

We can best appreciate the usage of the vertical bracket representation from an example. In the case of electrostatic actuation, $l^F = l^2$, and from Equation 7.23 one deduces $a = l^{-1}$, $t = l^1$, and for the power density $PV^{-1} = l^{-1}$ (an increase of a factor of 10).

For force laws with a power higher than l^2, the power generated per volume degrades as the scale decreases. Even in a case with $F = 1^4$, the time required to perform a task remains constant when the system is scaled down. This is an observation we understand intuitively: small things tend to be quick. We should keep in mind that beneficial effects are easily overshadowed by loss mechanisms, which scale in the same way or become even more important in the microdomain.

In Table 7.4 we list various physical phenomena and their scaling. The highest-order law is that for the moment of inertia (l^5); mass moment of inertia becomes rapidly unimportant for small-scale systems, and consequently small motors, both electric and combustion powered, are able to reach top speed much faster than large motors.

Scaling Examples

The Importance of the Surface-to-Volume Ratio

If a system is reduced isomorphically in size (i.e., scaled down with all dimensions of the system decreased uniformly), the changes in length, area, and volume ratios alter the relative influence of various physical effects that determine the overall operation in unexpected ways. For geometrically similar (isometric) objects of the same mass density, body mass (m), is proportional to the cube of the body length, l^3, and the surface area is proportional to l^2 or the surface-to-volume ratio (S/V) equals $l^{2/3}$, i.e., $l^{0.67}$.

Table 7.4 Scaling of a Selected Set of Physical Phenomena

Physical Quantity	Scaling Exponent of l	Units
Area	2	m^2
Bending stiffness	1	$N\ m^{-1}$
Buoyant force	3	N
Capacitance	1	F
Capacitor electric field	–1	Vm^{-1}
Deformation	1	m
Drag and lift forces	2 + 2n (n is fluid relative velocity)	N
Electrostatic energy	3	J
Electrostatic force	2	N
Frictional force	2	N
Heat capacity	3	$J\ K^{-1}$
Inductance	1	H
Magnetic force	4	N
Mass (m)	3	kg
Mass moment of inertia	5	$Kg{\cdot}m^2$
Ohmic current	2	A
Resistance	–1	Ω
Resistive power loss	1	$A^2\ \Omega$
Shear stiffness	1	$N\ m^{-1}$
Strength	2	$N\ m^{-2}$
Strength-to weight ratio	–1	m
Surface tension force	1	N
Thermal conductance	1	$W\ K^{-1}$
Thermal time constant	2	s
Viscous forces	1 + ν (ν is fluid relative velocity)	N
Voltage	1	V
Volume (V)	3	m^3

As isometric objects or organisms shrink in size, the S/V increases. The surface area of a smaller structure is relatively larger compared to its volume than that of a larger object. There are many examples in biology and daily experience to choose from to illustrate the pervasive importance of increasing S/V with decreasing size. The abundance curve of types of animals as a function of their size as shown in Figure 7.6 illustrates the importance of a change in S/V as a function of size. For warm-blooded mammals there are significant problems associated with being too small. The very small pygmy or dwarf shrew (about 4 cm long), for example, must eat continuously or freeze to death. The heat loss from a living creature is roughly proportional to its surface area (l^2), and the rate of compensating heat generation through eating is roughly proportional to its volume (l^3). As animals get smaller, a greater percentage of their energy intake is required to balance the heat loss. A warm-blooded animal smaller than the dwarf shrew or the Cuban bee hummingbird (about 5 cm) becomes improbable; it could neither obtain nor digest the food required to maintain its constant body temperature. Insects circumvent the problem of heat loss by being cold-blooded.

On the large end of the animal size spectrum, there are no land animals larger than the African elephant at 3.80 m. Land animals fighting the resistance of gravity can grow only so big before becoming too clumsy and inefficient. Large animals also find few niches on earth that can accommodate them, and as a consequence there are fewer large animals than small ones. For creatures of the sea, the same physical barrier of gravity to size does not

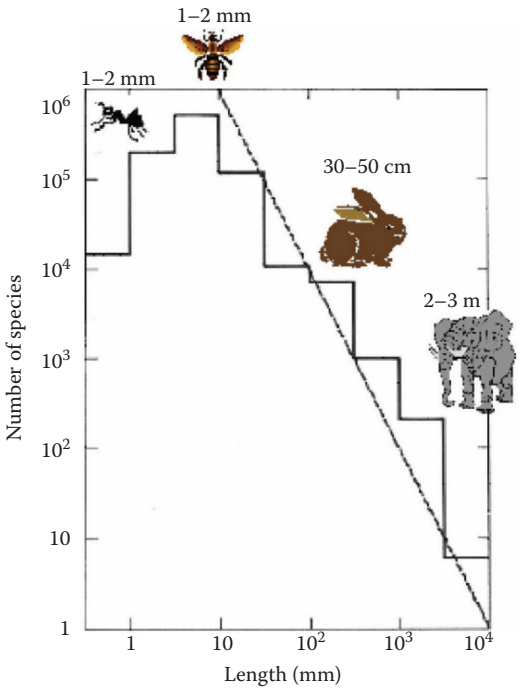

FIGURE 7.6 An abundance of types of animals in various size categories.

exist. The largest sea creature in volume is a blue whale, a little more than 20 m (60 ft.) long, much larger than the elephant. In terms of their length, the range of living things stretches over about 8 orders of magnitude, from the minute prokaryotic bacterium-like *Mycoplasma* (0.3 µm) to the massive blue whale (20 m).

At the small end of the size spectrum, smaller birds and animals are quicker and more agile, and insects are most plentiful. Scaling laws and the many niches in nature where they can hide and survive make insects perhaps the most successful animal species. Morowitz postulates that scaling laws must impose a lower limit for life in a dry environment even for cold-blooded animals, explaining why the abundance curve exhibits a peak.[8] Smaller organisms, because of their very large S/V, cannot retain their vital fluids long enough to survive, and no independent living organism (we exclude viruses) is smaller than the smallest bacteria at 0.2 µm. Water-based life increases its range of sizes both above and below that of terrestrial animals by evading gravity in the large-size range and drying out in the small-size range.

Faster evaporation in dry environments associated with larger surface-to-volume ratios also has important consequences for the retention of liquids in small biosensors, the evaporation of ejected drops in drop delivery equipment, the aqueous cocktails in miniaturized polymerase chain reaction (PCR) chambers, etc. In all these, evaporation quickly becomes a problem with decreasing drop size. Solutions include adding a hygroscopic material; mixing with solvents with lower vapor pressure (e.g., glycerol); topping of the solution with a low-vapor-pressure, nonmixing liquid; and working in a solvent-saturated environment.

Scaling in Surface Swimming

Earlier we mentioned the work on scaling in nature by Knut Schmidt-Nielsen, McMahon and Bonner, and Vogel in the context of Biomimetics (see also Chapter 2). In the same context, Hayashi presented an analysis of the natural laws that govern the relationship between speed and body length in water, on land, and in air.[9] Hayashi also analyzed the effect that miniaturization has on the strength of materials, various surface phenomena, and manufacturing accuracy. The latter is an aspect we covered in Volume II, Chapter 6, on mechanical energy-based removing. Here we will briefly look at scaling in surface swimming followed by an introduction to scaling in flight.

The resistance fish and other swimmers must overcome moving on the surface of a body of water is not gravity (l^3) but "skin friction," which increases only as the square of the linear dimensions (l^2). In this case, a larger size leads to a distinct advantage in that the larger the surface of the swimmer, the greater its swimming speed. This can be understood as follows. The available energy (E) for swimming speed (v) depends on the mass of the creature's muscles or engines (l^3), while its motion through water is opposed by the skin-friction resistance, R (l^2). This leads to $E \sim R \times v^2$ or $v \sim \sqrt{1}$; in other words, the bigger fish or the bigger ship moves faster, but only in the ratio of the square root of the increasing length. The latter is captured in the Froude number. The Froude number Fr is the ratio of inertial to gravitational forces. William Froude (1810–1879), British naval architect and engineer, realized that the factor that most limits the speed of ships or swimmers is the energy involved in the production

of waves by the swimmer and by noting that wave speed increases with the square root of the wavelength. Surface swimmers find it hard to go faster than the waves they create, and by making waves of longer length, the bigger swimmer makes waves that travel faster. Wave production depends on two forces, inertia and gravity. The inertia of the moving water keeps it wavy, and gravity tries to flatten the surface; the interaction of these two phenomena sets the speed of the wave. Surface swimmers thus vary in how they produce waves on the basis of their length, so replace the mass in Equation 7.24 by l^3 times density. Inertial acceleration is hard to measure, so we replace it by velocity divided by time and obtain Equation 7.25. Time in Equation 7.25 can be gotten rid of by noting that length over time is velocity, and the Froude number is obtained in Equation 7.26.

$$\mathrm{Fr} = \frac{ma}{mg} \tag{7.24}$$

$$\mathrm{Fr} = \frac{\rho l^3 v t^{-1}}{\rho l^3 g} \tag{7.25}$$

$$\mathrm{Fr} = \frac{\rho l^3 v t^{-1}}{\rho l^3 g} = \frac{\rho l^2 v^2}{\rho l^3 g} = \frac{v^2}{gl} \tag{7.26}$$

Scaling in Flying

Aircraft and ocean liners operate in fluid environments with a range of Reynolds numbers in the millions to hundreds of millions because the viscous forces are small compared with inertial forces (see Volume I, Equation 6.71). At the other end of the spectrum are small insects, birds, and fish, whose viscous forces are of the same order of magnitude as the inertial forces. Obviously, depending on size, different strategies will be required for both flying and swimming. Although the same fluid mechanical rules govern motion through air and water, flying, as Icarus could attest (see the inset heading Chapter 2, this volume), is considerably harder than swimming. The lower density of air helps a flying machine go forward faster (thrust), but it necessitates a larger force to keep it aloft. For an object to hover immobile in air takes an upward force that counterbalances weight, while forward thrust requires a force equal to the drag force (F_D) at its specific flying speed. Weight depends on volume, while drag depends on area. Thus the smaller creature finds weight less troublesome, but drag becomes a real "drag"—in other words, for a tiny insect, staying aloft against gravity's pull is easy but making headway against the drag of the air is tougher than for a bird or a plane.

The drag coefficient C_D, a dimensionless number, is given by $C_D = F_D/\rho\, l^2 v^2 = f\,(\mathrm{Re})$ (Equation 7.8), with surface area A replacing l^2 and a factor 1/2 added:

$$C_D = \frac{F_D}{\frac{1}{2}\rho v^2 A} \tag{7.27}$$

where ρ = density of the fluid
v = free stream velocity
A = characteristic area of the body*
F_D = drag force

The drag coefficient, C_D, is the parameter that best describes the resistance to motion. As we gleaned from Equation 7.8, the drag coefficient varies with the Reynolds number, but the coefficient also depends on the angle of attack (AOA). This is the angle that the flying object penetrates the air with. It is measured in degrees. In the case of an airfoil (Figure 7.7), at zero degrees AOA, the front of the airfoil is pointed directly into the stream. At a 90° AOA, it is pointed straight up.

We learned in Volume I, Chapter 6, on fluidics, that C_D also depends on surface roughness; the drag coefficient decreases with increasing roughness as it delays the boundary layer separation. In Figure 7.8A we show the historical reduction in drag on cars. The C_D of a Porsche 924 Turbo, for example, is 0.34, while that for a Toyota Tercel (liftback) is 0.54. In Figure 7.8B we also show the drag coefficient of some different familiar shapes.

Lift force, F_L, is the force normal to the direction of the object's velocity, v. Lift force, like drag force, depends on surface area and goes up with the object's

* A = frontal area (thick body, cylinder, cars, projectiles) = plan area (wide/flat body, wings, hydrofoils) = wetted area (surface ships, barges). This is a simplification, as both frictional and pressure drag forces should be considered, and factor A has a different meaning in both. For a more rigorous treatment, see Granger.[6]

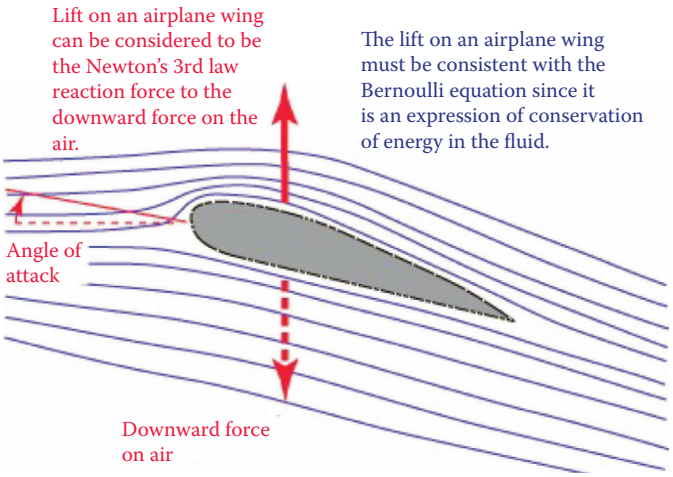

FIGURE 7.7 Angle of attack of an airfoil. For Bernoulli equation, see Volume I, Chapter 6, on fluidics (Equation 6.44). Notice that the Bernoulli interpretation of lift is not entirely correct (see below).

speed through the air. Many of us were taught that airplanes fly as a result of the Bernoulli's principle, which says that if air speeds up, pressure is lowered (Volume I, Equation 6.44). From the shape of the wing shown in Figure 7.7 the path over the top is longer than over the bottom, and in the Bernoulli model a wing generates lift because the air goes faster over the top, creating a region of low pressure, and thus lift. This begs the question of how inverted flight is possible, and naturally one may also ask why the air goes faster over the top of the wing than over the bottom. The usual explanation is that when the air separates at the leading edge of the wing, the part that goes over the top must converge at the trailing edge with the part that goes under the bottom. This is the so-called *principle of equal transit times* (http://www.allstar.fiu.edu/AERO/airflylvl3.htm, http://www.grc.nasa.gov/www/K-12/airplane/

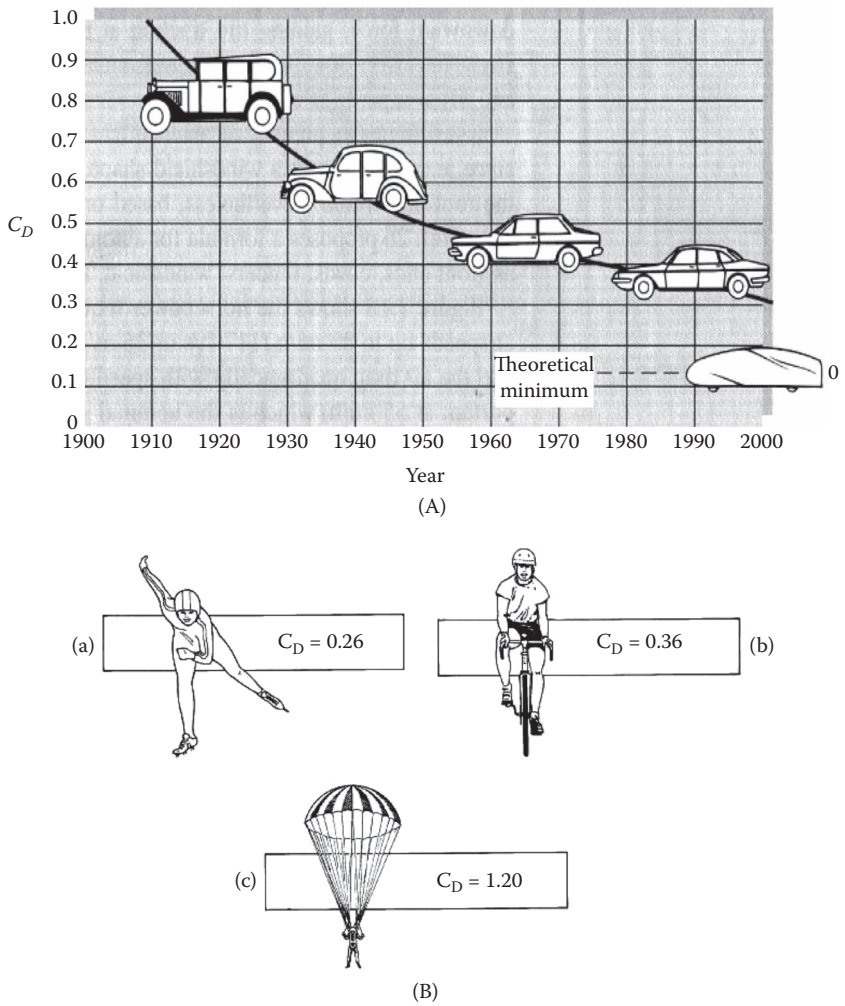

FIGURE 7.8 (A) Historical reduction of drag on cars. (B) Drag on a variety of shapes: (a) skater; (b) cyclist; (c) parachutist.

lift1.html). But in a wind tunnel simulation, where colored smoke is introduced, one sees that the air that goes over the top of the wing gets to the trailing edge before the air that goes under the wing. In fact, closer inspection reveals that the air going under the wing is slowed down from the "free-stream" velocity of the air. A calculation of the average speeds of the air over and under the wing can be made, and from the Bernoulli equation the resulting pressure forces and thus lift can be determined. The problem is that this calculation shows that in order to generate the required lift for a typical small airplane, the distance over the top of the wing must be about 50% longer than under the bottom; this would make for a very odd wing shape. An airplane wing more typically has a top surface that is only 1.5–2.5% longer than the bottom surface. So a Cessna 172 would have to fly at over 400 mph to generate enough lift. Clearly, something in this description of lift is wrong. As Newton's laws suggests, the wing must change something of the air to get lift, and that something, as revealed from wind tunnel tests, is that air passes over the wing and is bent down. The bending of the air is the action, and the reaction is the lift on the wing. The natural question now becomes, how does the wing divert the air down? When a moving fluid, such as air or water, comes into contact with a curved surface, it tries to follow that surface; this is known as the *Coanda effect*. The reason behind the Coanda effect is viscosity; viscosity in air is small, but it is enough for the air molecules to want to stick to the wing surface. Because the fluid near the surface has a change in velocity, the fluid flow is bent toward the surface. When the air is bent around the top of the wing, it pulls on the air above it, accelerating that air down; otherwise there would be voids left in the air above the wing. This pulling causes the pressure to become lower above the wing. It is the acceleration of the air above the wing in the downward direction that gives lift. The lift of a wing is equal to the change in momentum of the air it is diverting down.

The dimensionless lift coefficient C_L is given by the following equation:

$$C_L = \frac{F_L}{\frac{1}{2}\rho v^2 A} \tag{7.28}$$

Both lift and drag coefficients are a function of the Reynolds number, AOA, geometric shape (i.e., the thickness distribution), and speed. The lift and drag forces can be changed by changing (most easily) the AOA or velocity (v). The surface area (A) can also be changed by changing the shape or configuration of, say, the wing flaps during flight. As in swimming, larger objects mean faster flight: a fruit fly might hit 3 mph, a bumblebee can do about 12 mph, and a Boeing 747 can do 920 kph.

Doubling the length of a wing gives a flying machine four times the lift (and drag), but it also increases the weight by a factor of 8. The best-designed wings produce a lot of lift while suffering little drag. The largest flying animals alive today are the soaring birds such as the 10-kg wandering albatross, with a wingspan of 3.5 meters. Lift relative to drag gets worse as wings get smaller, and gliding becomes impossible with wing lengths of less than 1 mm.[10] As a point of reference, ordinary airplanes have a lift/drag ratio of 10–100, whereas that of a micromachined airplane fabricated from Si by Kubo et al. (1.56 mm long and with a mass of 10.8 mg) was measured at 0.4.[11] The low lift/drag ratio of the latter is due to the influence of viscosity, which gets more pernicious the smaller the flying object. When a glider descends, the angle depends entirely on the ratio of lift to drag. The larger this ratio, the more horizontal the glide. Kubo et al.'s micromachined airplane had an AOA less than 45°, so it could not glide. Small flying animals use fast-beating wings to produce both lift and thrust. Their wings not only beat up and down but to some extent also fore and aft. The drag force produced by down beating must exceed that produced by up beating.

Scaling in Surface Tension and Adhesion

Inertia and gravity forces rule the world of large organisms and machines, while the forces of attraction between molecules rule the world of minute organisms. A large and lumbering elephant cares little about viscosity and even less about surface tension and diffusion, but insects are similar in size to many human-made miniature machines, and viscosity, surface tension, and diffusion play an important role for both.

Capillary forces, as we saw above, are caused by surface tension and provide a striking example of scaling laws. The mass of a liquid in a capillary tube, and hence the weight, scales as l^3 and decreases more rapidly than the surface tension, which scales as l, as the system becomes smaller. That is why it is more difficult to empty liquids from a capillary than to spill coffee from a cup.

One easily recognizes how insects take advantage of surface tension and several other scaling phenomena: some insects can walk on water (e.g., a water strider), and most jump farther in proportion to their size than humans can. Walking on water is based on the surface tension at the water surface (l^1), which easily supports an insect's weight (l^3). A 10-mg, mosquito-sized insect needs a mere millimeter of total foot edge to be supported by surface tension; a 60-kg human would need 8000 m of foot edge. The effort for a jump is proportional to the mass (m) and the height (h) to which that weight is raised. In other words, $E \sim m \times h$. The biological force in a muscle available for this work is proportional to the mass of the muscle or to the mass of the animal. It follows that h is, or tends to be, a constant. As a consequence, animals tend to jump to the same actual height independent of their size. Insects have other advantages: to circumvent problems with excessive heat loss, insects are cold-blooded. Having adapted so well to so many niches in nature, it is no wonder insects are so abundant (Figure 7.6).

As we saw in Volume I, Chapter 7, molecular adhesive forces increase in proportion to the surface l^2. The strength of the attraction force between two solid surfaces drops off very quickly, though, as the distance between the two solids increases (see Volume I, Equation 7.26 and Table 7.8). The larger the bodies, the smaller the chance they come in close contact, and intimate contact is greatly aided by small size. Bonner suggested that adhesive forces, just like surface tension, scale as l^1. In Figure 7.9, following Bonner,[4] we plot the forces due to mass (l^3) and molecular cohesion (l^1) (both surface tension and adhesion) as a function of length in a log-log plot. The vertical axis measures force in arbitrary units. The lines for l^3 and l^1 are made to cross arbitrarily at 1 mm, based on the empirical observation that structures of that length have to deal in

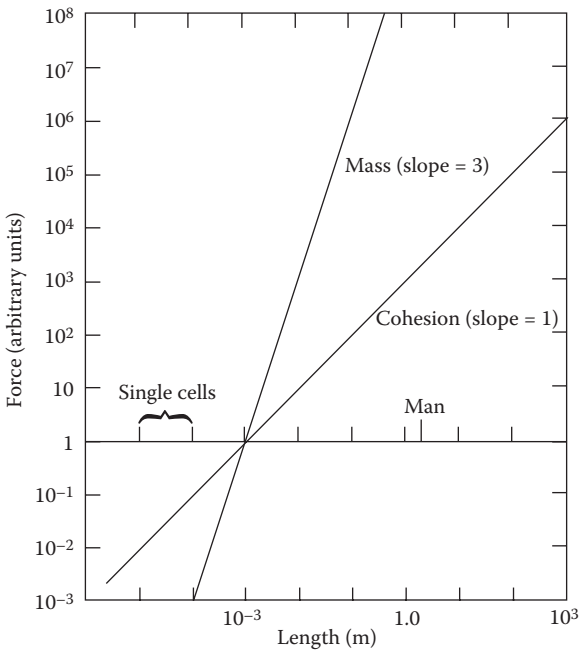

FIGURE 7.9 Log-log plot of forces due to mass (l^3) and molecular cohesion (l^2) (both surface tension and adhesion) as a function of length. The vertical axis measures force in arbitrary units. The lines for l^3 and l^1 are made to cross arbitrarily at 1 mm.[4]

equal amounts with the impact of gravity and cohesion forces. This graph helps explain how creatures below a certain size, can walk on walls and ceilings. Protuberances on the feet of these creatures function to enhance the molecular adhesion. From Figure 7.9, we see that small insects and other wall-walking animals must operate below a critical size at which the line proportional to body weight intersects the line proportional to cohesive force.

Kellar Autumn et al. confirmed, using a MEMS force sensor, that in the case of a gecko, the gecko setae (microhairs) are responsible for the remarkable van der Waals-based dry adhesion to walls.[12] This effect is almost exclusively based on the size and shape of the gecko's foot hair or setae and is quite independent of surface chemistry. Gecko foot hair is made of five microdiameter seta fibers, and each of these fibers is equipped with between 100 and 1000 nanofibers (spatulae), which are 200 nm in diameter (see Figure 7.10 for a picture of a gecko, a gecko foot, setae, and spatulae). In order for this type of dry and clean adhesion (the hairs are hydrophobic in nature) to work, only a small preload force normal to the surface is required to force the compliant

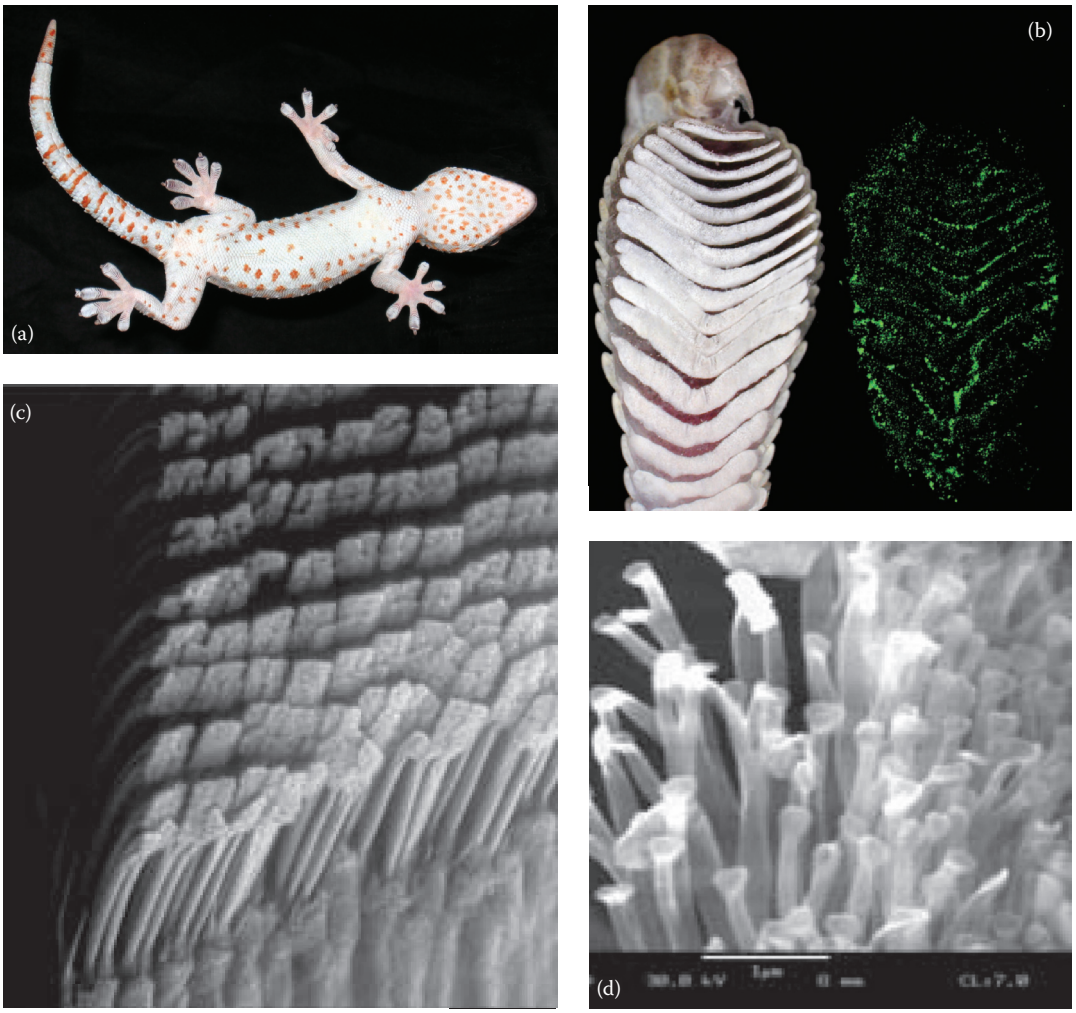

FIGURE 7.10 A gecko (a), gecko foot (b), setae (c), and spatulae (d). (Courtesy of Dr. K. Autumn, http://www.lclark.edu/~autumn/PNAS.)

hairs to configure themselves properly to a rough or smooth surface. The adhesion force can be as high as 10 N per 1 cm^2 area, and the foot will remain on until peeled off. Menon et al. have been working on synthetic gecko hair to enable gecko inspired climbing robots.[13] For an update on gecko adhesion, visit http://www.lclark.edu/~autumn/PNAS.

Scaling and Diffusion

Diffusion plays a particularly significant role in the lives of very small organisms. Diffusion is the consequence of the endless and random wandering of every molecule of every gas or liquid at temperatures above 0 K. Diffusional effects come into play at yet a smaller length scale than surface tension. For a spherical molecule, the Stokes-Einstein diffusion coefficient, D (m^2/s), we saw in Volume I, Chapter 6, is given by (Volume I, Equation 6.29) the following:

$$D = \frac{k_B T}{6\pi\eta r} \qquad \text{(Volume I, Equation 6.29)}$$

where k_B = Boltzmann constant ($1.38 \times 10\, m^{-23} J\ K^{-1}$)
T = absolute temperature (K)
η = absolute viscosity (kg/m·s)
r = hydrodynamic radius

A small molecule, with a molecular weight of between 500 and 1000, will have a diffusion coefficient of about 5×10^{-5} m^2/s. According to the random walk equation, the diffusion length, x, of a molecule in solution is given by the Einstein-Smoluchowski expression (Volume I, Equation 6.100):

$$x = \sqrt{2D\tau} \qquad \text{(Volume I, Equation 6.100)}$$

Table 7.5 A Drop of Saline Solution in a Small Bucket

Volume	1 μL	1 nL (10^{-9} L)	1 pL (10^{-12} L)	1 fL (10^{-15} L)	1 aL (10^{-18} L)

where τ is the time required for a molecule to diffuse over a distance *x*. From Volume I, Equation 6.100, diffusion of a molecule in the bulk of a liquid over a length of 10 μm is a million times faster than diffusion over 1 cm. Table 7.5[14,15] illustrates how the volume of a drop of liquid (say, of a saline solution, in liters), relates to the linear dimension of a cube containing it. Assuming a diffusion constant *D* of 10^{-5} cm^2s^{-1}, the table also lists the time it takes for a molecule to diffuse across one side of the containment volume; it will take a molecule about 500 s to diffuse over a distance of 1 mm but only 0.5 ms to cross a distance of 1 μm. Finally, the table lists the total number of molecules the various volumes filled with a 1 μM solution contain.

As we saw in Volume I, Chapter 6, on fluidics, mixing, although only mediated by diffusion, is very fast at the microlevel and should allow for reaction times to be determined by inherent kinetics rather than the time it takes for reactant species to meet in solution. In nature, only the smallest animals rely on diffusion for transport; animals made up of more than a few cells cannot rely on diffusion anymore to move materials within themselves. They augment transport with hearts, blood vessels, pumped lungs, digestive tubes, etc. These distribution networks typically constitute fractals. Fractals are an optimal geometry for minimizing the work lost due to the transfer network while maximizing the effective surface area. Along this line, one can envision making arrays of parallel microchemical reactors. Mixing small amounts of fluid in a large set of these parallel microreactors leads to a much higher mixing and reaction efficiency than when mixing the same total amount of reagents in one big reactor vessel all at once. Based on the latter, it is possible to design chemical reactors where scaling up is perfectly linear, a feat not possible when scaling up chemical reactors in the traditional mode from milliliters to hundreds of liters in big tanks.

Mixing of liquids in small microfluidic manifolds is addressed in Volume I, Chapter 6, on fluidics.

Scaling of Strength-to-Weight Ratio and Inertia

From the previous section, we recognize the important role of gravity for larger systems. Gravity, for example, does not allow large creatures to support themselves with surface tension on the surface of water. It makes large objects fall faster than small ones and necessitates that larger aircraft fly faster to stay aloft. To counteract gravity, large land mammals have stiffer bones than small animals and require thicker legs. The legs of the elephant appear as rather straight, stubby columns, while those of an insect are long and spindly. The diameter of a tall homogeneous body such as a tree must grow as the power 3/2 of its height, which accounts for Goethe's *Es ist dafür gesorgt, dass die Bäume nicht in den Himmel wachsen** in *Dichtung und Wahrheit*.[16] Human design reflects the same influence. If we build two geometrically similar bridges, the larger will be the weaker of the two, and it will be so in the ratio of their linear dimension, *l*. The strength of the iron girders in the two bridges varies with the square of the linear dimension, that is, l^2, but the weight of the whole structure varies with the cube of its linear dimension,

* Translation: It has been arranged for trees not to grow all the way into heaven.

that is, l^3. Scaling up the entire bridge by a factor of two gives us columns that are four times as strong but must also bear eight times the load—the safety factor is halved. The girders, being thicker, also suffer greater self-loading, which requires them to be thicker yet. To engineer around gravity, stiffer materials and alternative designs are required. The larger the structure is, the more severe the strain. By reducing the size of a device, the structural stiffness generally increases relative to inertia-imposed loads.

The strength-to-weight ratio scales as l^{-1} (area over weight, i.e., l^2/l^3), and as a consequence small things are relatively stronger. Consider the strength comparison between a human and an ant. The human body is 300 times that of an ant, and a human can carry approximately one body weight. The strength-to-weight ratio law predicts that a 1/300th scale human Lilliputian could carry 300 times its body weight. Although not exactly right, an ant can carry objects 10–50 times (but not 300 times) its own weight. The discrepancy is caused by the difference between a scaled human form to that of an ant. Because of the increased strength-to-weight ratio, an ant is proportionately more slender than a human; in other words, an ant scaled to human size would have legs far too thin to support its own weight.

Inertia is the tendency of both fluids and solids to remain at rest or to keep moving. The force involved in starting a movement or stopping it equals the mass of the object times the acceleration or deceleration. The highest-order scaling laws are those involving moments of inertia, that is:

$$I = \int r^2 dm \tag{7.29}$$

with l^5. Small things are easier to start and stop. An example of this is small motors, electric or combustion, which are able to reach top speed in a fraction of a second; large motors may require several seconds to reach full speed.

An important bottleneck in the development of microactuators in general is that resistive forces, such as viscous drag (l^2) and surface tension (l), exceed motive forces [mass (l^3) × surface (l^2) = (l^5)] in the microdomain. Miniaturization engineers look for driving forces that scale more advantageously, such as electrostastics (l^2) and capillary force (l).

The above scaling examples constitute but a few illustrations; many more scaling examples can be found in Chapter 8, this volume, on actuators; Volume I, Chapter 6, on fluidics; Chapter 9, this volume, on power and brains in miniature devices; and throughout the book.

Breakdown of Scaling Laws

Introduction

Scaling laws break down when the continuum theory for the phenomenon under study no longer applies. The latter occurs any time boundary conditions for the macroscale case are violated. Many examples of breakdown of scaling laws can be found throughout the book. A detailed example was worked out in Volume I, Chapter 7, where we saw that electrochemical detectors with electrodes of the size of the diffusion boundary layer thickness display noncontinuum behavior. Here we give as an additional example, namely that of electrostatic devices with electrode spacing of the size of the mean free path of the surrounding gas molecules.

Scaling in Electrostatics

Boundaries and Continuum Theory in Electrostatics

Electrostatic charges, we will see in Chapter 8, on actuators, arise from buildup or deficit of free electrons in a material. An electrically charged material can exert an attractive force on oppositely charged objects or a repulsive force on similarly charged ones. To appreciate scaling issues in electrostatics, we follow Trimmer's analysis of isometric scaling of the maximum stored energy in a simple parallel plate capacitor. The ability of a capacitor, C, to store charge is its capacitance, C, and the capacitance is related to the applied potential V as $C = Q/V$. From Gauss's law (Volume I, Equation 5.37) applied to two plates of cross-sectional area A, containing a dielectric (and hence charge density Q/A), one obtains the following:

$$E = \frac{Q/A}{\varepsilon_r \varepsilon_0} \tag{7.30}$$

and since C = Q/V and E is given by V/d, where d is the distance between the two plates of the capacitor, Equation 7.30 can be rewritten as follows.

$$C = \frac{\varepsilon_r \varepsilon_0 A}{d} \tag{7.31}$$

From Equation 7.31, it is clear that the greater the relative permittivity ε_r, of the material between the capacitor plates, the greater the capacitance. This can be understood as follows, since a dielectric is an insulator all a gap material can do in response to a charge on the capacitor plates is to accumulate a countercharge. The greater the relative permittivity, the greater the effect of this charges redistribution; thus the greater the effective "stored charge." Based on Equation 7.30, the insertion of a dielectric reduces the electric field inside the dielectric by a factor ε_r.

The dimensions of the capacitor in Figure 7.11 are w, v, and d, and they all scale with l. We first calculate the incremental work dW to add charge dQ to this capacitor at voltage V:

$$dW = V(Q) \cdot dQ = \left(\frac{Q}{C}\right) \cdot dQ \tag{7.32}$$

The total work W to charge to Q and thus the energy stored in the capacitor is then given as follows:

$$U = W = \frac{1}{C}\int_0^Q Q\, dQ = \frac{1}{2}\frac{Q^2}{C} = \frac{1}{2}CV^2 \tag{7.33}$$

Above a critical voltage, V_b, the electrostatic forces polarizing the molecules in the gap are so strong that electrons are torn free and charge flows and the maximum electrostatic potential energy, U_m, stored in the capacitor in Figure 7.11 is then given by the following:

$$U_m = \frac{1}{2}CV_b^2 = \frac{\varepsilon_r \nu_0 w v V_b^2}{2d} \tag{7.34}$$

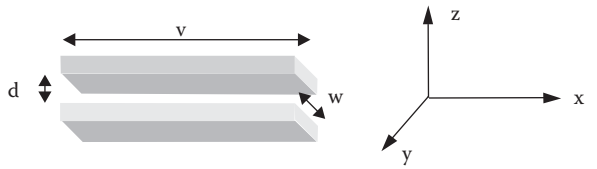

FIGURE 7.11 A parallel plate capacitor of plate size $w \times v$ and separation d stores a maximum potential energy of U_m.

where V_b = electrical breakdown voltage and $\varepsilon_r\varepsilon_0 \times w \times v/d$ = capacitance C. The permittivity of vacuum, ε_0, and the relative permittivity, ε_r, remain unchanged with scaling, so we can assign them an l^0 dimension. We also assume, for now, that V_b scales linearly with d. Intuitively, we expect a smaller gap, d, to result, indeed, in a lower breakdown voltage, V_b. However, as we shall see next (contrary to our macrointuition), at very small capacitor plate separation, the linear relationship between V_b and d breaks down. The breakdown voltage of the capacitor actually starts increasing with decreasing plate separation (see discussion below on continuum breakdown in electrostatics and the discussion on the Paschen curve below, in Figure 7.12).

Writing out all the dimensions in Equation 7.34 in terms of l, we obtain the following:

$$U_m \propto \frac{l^0\, l^0 l^1\, l^1\, (l^1)^2}{l^1} = l^3 \tag{7.35}$$

and the maximum energy stored in the capacitor scales as l^3. It follows that if l decreases by a factor of 10 (i.e., w, v, and d all decrease simultaneously), the stored maximum potential energy in the capacitor decreases by a factor of 1000.

The maximum electrostatic energy density, U'_m (in J/m^3), between the capacitor plates is obtained from Equation 7.34 by dividing the maximum potential energy, U_m, by the volume, V_0, of the capacitor gap, $V_0 = w \times v \times d$:

$$U'_m = \frac{\varepsilon_r \nu_0 E_b^2}{2} \tag{7.36}$$

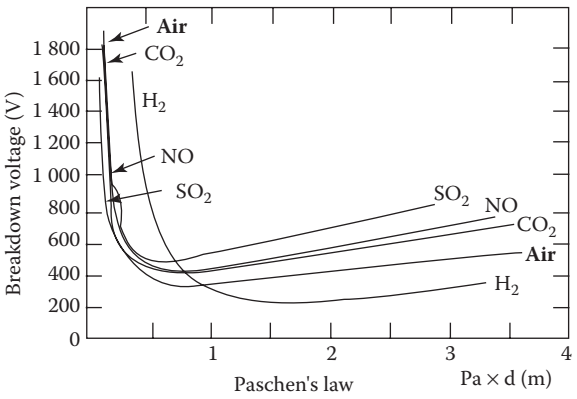

FIGURE 7.12 Breakdown voltage between two conductors, plotted as a function of the product of the distance between them and the surrounding gas pressure (P).

This expression for the energy density is general and is not restricted to the special case of a constant field in a parallel plate capacitor. In the case of an air capacitor, E_b is limited to approximately 3×10^6 Vm^{-1} by the electrical breakdown of air. Thus, the stored energy for an air capacitor is about 40 Jm^{-3}.[17] In power capacitors (see Chapter 9, on power and brains in miniature devices), with special dielectrics and a field of 10×10^6 Vm^{-1}, energy densities of 1 kJm^{-3} have been achieved.

We are interested in using electrostatic force in all types of actuators (see Chapter 8, on actuators), and that force, F, is the negative spatial derivative of the energy, U. In a case where we move the plate of a capacitor with respect to the other plate, the electric force will be the spatial derivative, in that direction, of the stored energy U. A translational movement of one plate with respect to the other in a microactuator in the direction x leads to a force, F_x, as follows:

$$F_x = -\frac{\partial U}{\partial x} = \frac{V^2}{2}\frac{\partial C}{\partial x} = \frac{l^3}{l^1} = l^2 \qquad (7.37)$$

where V is the applied voltage. The electrostatic force for a constant field is thus found to scale as l^2. This is often an advantage, because the mass and, hence, inertial forces scale as l^3. The electrostatic force gains over inertial forces as the size of the system is decreased. A decrease in size by a factor of 10 leads to a decrease of the inertial forces by a factor of 1000, whereas the electrostatic force decreases by a factor of only 100. It is thus not hard to exert rapid accelerations in microsystems with the aid of electrical fields. These are the type of features we will explore further in different types of electrostatic actuators in Chapter 8.

Breakdown of Continuum Theory in Electrostatics

We will now consider where macroscopic electrostatic laws err in the microscopic regime. The fundamental boundary condition in a gas pertains to the main free path, λ, the average distance traveled by a molecule between two successive collisions. The mean free path, λ, can be derived from the kinetic theory of gases as follows:

$$\lambda = \frac{1}{\sqrt{2}\pi n a^2} = \frac{kT}{\sqrt{2}\pi P a^2} \qquad (7.38)$$

where n = density (the number of molecules per unit volume)
T = temperature
k = Boltzmann constant
P = pressure
a = size of the molecule

Using Avogadro's number, we know that at room temperature and 1 atmosphere, 1 cm^3 contains 2.69×10^{19} molecules. Assuming that oxygen and nitrogen have a molecule size of about 3 Å, one calculates then a mean free path in air of about 60 nm.

Electrostatic charges, we saw earlier, arise from buildup or deficit of free electrons in a material. An electrically charged material can exert an attractive force on oppositely charged objects or a repulsive force on similarly charged ones. At small distances between two conductors in air, the electrical field is not isotropic as assumed above. This can be gleaned from the so-called *Paschen curve* in Figure 7.12. This figure represents the breakdown voltage between two conductors, plotted as a function of the product of the distance between them and the surrounding gas pressure (P). In the case of an air capacitor, the field strength required to cause sparks between the two electrodes (E_b), we saw in the section above, is approximately 3×10^6 Vm^{-1}. The general shape of the Paschen curve can be understood more easily by assuming that the pressure, P, remains constant at 1 atm, thus making the x-axis a simple distance axis. We notice that, on the right side of the Paschen curve, at large electrode distances, the field is constant and the scaling laws introduced above all pertain. But for smaller electrode gaps (below about 5 μm in air), the curve sharply reverses, bending upward and leading to higher electrical breakdown fields for thinner air gaps. Electrical breakdown in these small gaps does occur at much larger voltages than those predicted from linear scaling. From Bart et al.[17] and Busch-Vishniac[18] and references therein, we quote observed electrical fields of $10^8 \times$ Vm^{-1} (1.5-μm air gap), 1.7×10^8 Vm^{-1} (2-μm air gap), and 3.2×10^7 Vm^{-1} (12.5-μm air gap). The upper limit is the electrical field measured for small gaps in vacuum, that is, 3.0×10^8 Vm^{-1}.[19] Surface roughness results in a

lower average breakdown voltage, but even then, these fields are significantly higher than the 3×10^6 Vm^{-1} quoted above for breakdown of capacitors with large air gaps. Assuming a field strength of 3×10^8 Vm^{-1}, Equation 7.36 predicts an energy density of about 4×10^5 Jm^{-3}, compared with 40 Jm^{-3} without the Paschen effect. This unexpected result derives from the fact that there are not enough ionizing collisions to induce an avalanche between electrodes with a separation comparable to the mean free path of the surrounding gas. When the gap between two conductors approaches the mean free path of the molecules (λ), statistically fewer molecules are present to be ionized between those closely spaced conductors. Higher fields and higher-energy densities can be achieved before the critical breakdown voltage, V_b, is reached. The Paschen curve also illustrates, how, in terms of influencing the breakdown voltage, reducing the gap between two electrodes is equivalent to reducing the surrounding gas pressure: the x-axis is the product of pressure (P) and distance (d), and they exert the same effect on the breakdown voltage. One can thus actually say that reducing the distance between two conductors in a gas is equivalent to reducing the pressure in a macroscopic set-up.

In addition to the advantage of higher-energy densities in micromachined electrostatic systems, the Paschen effect suggests yet another advantage. The scaling of the electrical field (E_b) in the nonisotropic region is more like $l^{-1/2}$. According to Equation 7.37, in the macroregime, the force on a capacitor scales as l^2, or as a surface force. In the Paschen regime, the force scales with l so that with a factor of 10 size reduction, the inertial force still decreases by a factor of 1000, but the electrostatic force decreases only by a factor of 10. On the basis of Equation 7.23, we further see that acceleration and transit times are also higher than for the isotropic system.

Working on the left side of the Paschen curve renders high-field operation possible for a wide variety of electrostatic microdevices without incurring catastrophic sparking. Examples include the electrostatic motors illustrated in Figure 8.5, the electrostatic switch in Figure 8.19, and the author's volcano ionization sources presented in the example below.

Example: Ion Mobility Spectrometer

In an ion mobility spectrometer (IMS), ions produced at atmospheric pressure in an ionization cell by a ^{63}Ni beta source are accelerated in a drift chamber (uniform field of 150–250 V/cm), where they are separated according to their mobilities, detected as a current on a Faraday plate, and plotted on a time axis in accordance with their time of arrival (see Figure 7.13). About twenty years ago, this author set out to micromachine some critical components of an IMS instrument. We recognized that field uniformity, temperature, and pressure could be controlled with micromachined Si sensors. Our aim, though, was to substitute the ^{63}Ni ionization source

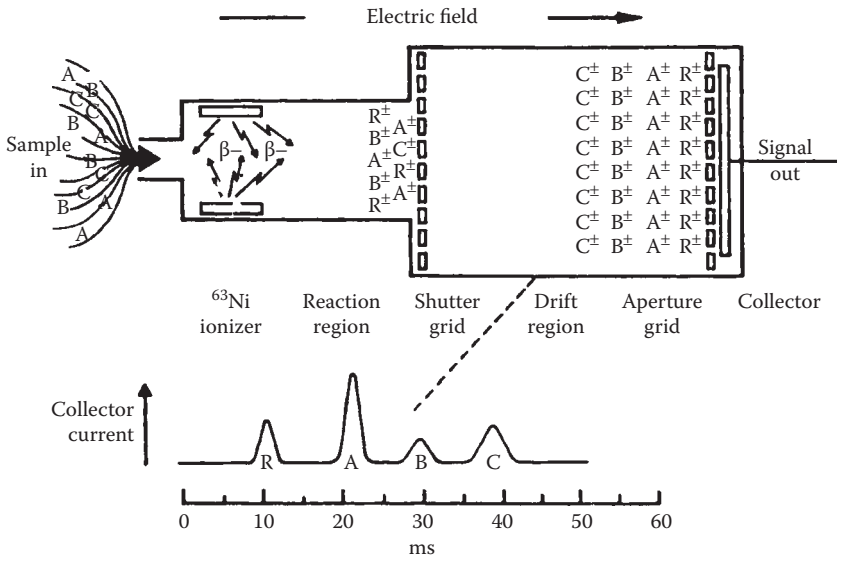

FIGURE 7.13 Ion mobility spectrometry with a Ni ionization source.

with a less fragmenting ionization source employing a "softer" field ionization (FI) technique. In FI, one creates mainly positive parent ions (M^+), and thus simpler spectra for complex environmental gas mixtures result. FI is well known from FI mass spectrometry (FIMS). But mass spectrometry is carried out in vacuum, and considering the extreme electric fields required for FI, one might expect that, under atmospheric pressure conditions, catastrophic electrical breakdown between the ionizing electrodes would occur. The idea about how to avoid breakdown or sparking at atmospheric pressures is based on the peculiar behavior of microelectrodes operating at the left side of the Paschen curve (see Figure 7.12), where much higher voltages are required for breakdown to occur.

For an ionization source operating on the left side of the Paschen curve, we microfabricated an array of microvolcanoes with a typical throat opening of 1 μm and a volcano rim to gate distance of less than 1 μm. Both the volcano rim and gate electrode may be made from a variety of inert metals. A scanning electron microscope (SEM) photomicrograph of a single microvolcano and an array of microvolcanoes is shown in Figure 7.14a (the metal used in this case is Pt). Given the small dimensions of the microvolcanoes, the intense electric fields required for field ionization can be produced with significantly

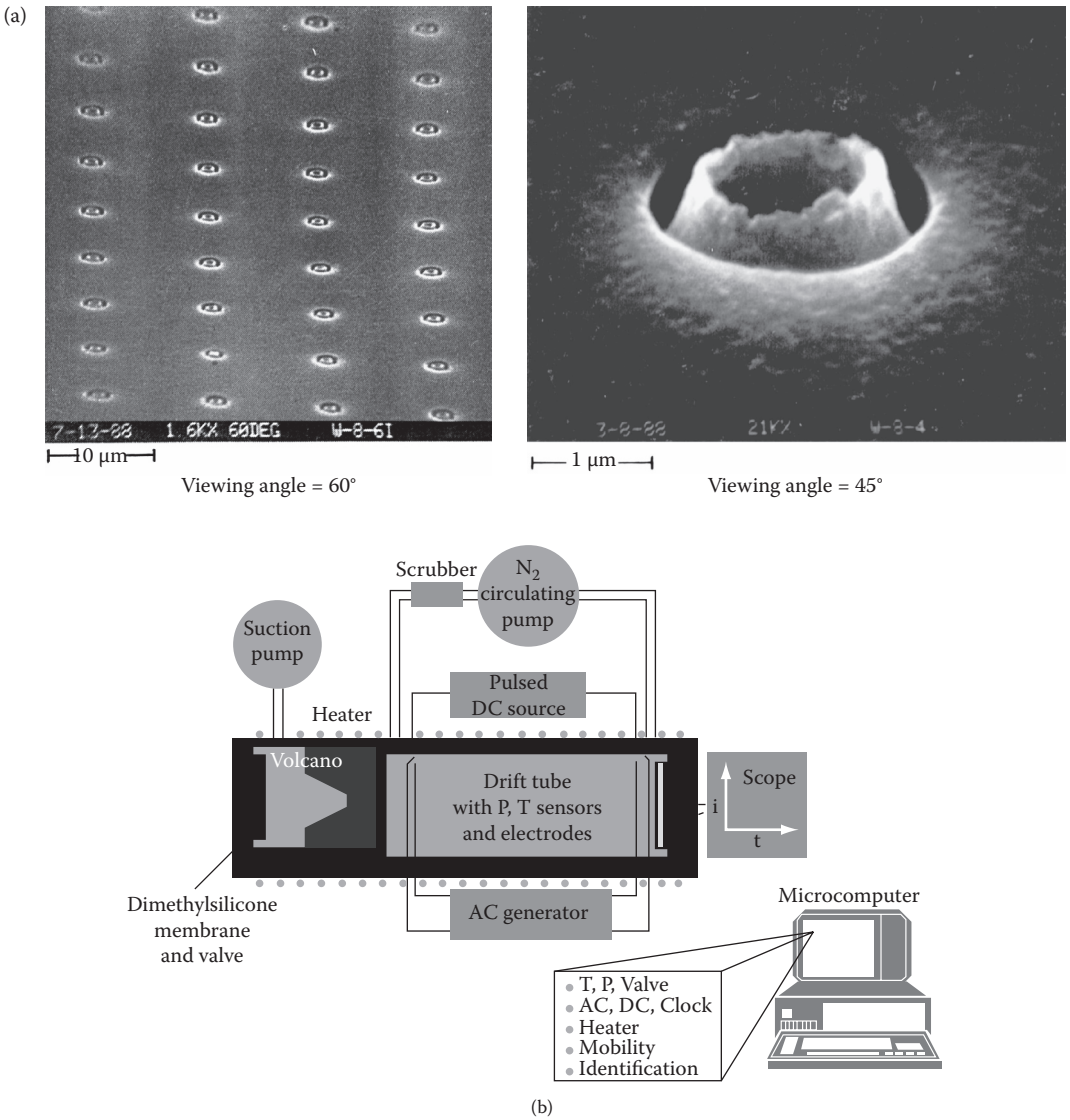

FIGURE 7.14 Ion mobility spectrometry with micromachined volcano sources. (a) Scanning electron microscope image of micromachined volcanoes. (b) Setup for ion mobility spectrometry with microvolcano ionization sources.

lower voltages than other FI sources. Referring back to the Paschen curve, it is clear that the microvolcano sources should operate at atmospheric pressure with voltages up to several hundred volts and perhaps as high as a kilovolt before they induce sparking. In collaboration with Dr. M. Coggiola, at SRI International, we did show that these sources can indeed resist electrical breakdown at atmospheric pressure and produce usable current levels from positive ions formed from gases such as pyridine, butane, and toluene in a setup like that shown in Figure 7.14b.[20]

The fabrication process of the microvolcanoes, which are embedded in a brittle 1-μm-thick Si dioxide layer, was very problematic, and failure rate was very high. Sturdier, more reliable volcano sources are needed to continue this type of development. Today, much better, high-aspect-ratio micromachining techniques are available, and it would be very worthwhile to reinitiate such a study.

Questions

Questions by Omid Rohani, UC Irvine

7.1: What do you expect will be the influence of miniaturization on a potentiometric sensor and on an amperometric sensor?

7.2: Explain in detail the scaling laws for flying and swimming.

7.3: The surface waves in water are characterized by an angular velocity ω and a wave number $k = 2\pi\lambda$ (λ, wavelength). In this problem we intend to find a dispersion relation expressing ω as a function of *k*.

(a) Using Buckingham's π theorem, find a dispersion relation containing ω and *k*. Accept that the depth *d*, the wave height *h*, the acceleration of gravity *g*, the waters density ρ, and the water surface tension γ play roles in this problem and neglect the water viscosity.

Appendix 7A: Common Dimensional Numbers

Parameter	Definition	Qualitative Ratio	Importance of Effects
Reynolds number	$R_E = \rho UL/\mu$	Inertia/Viscosity	Always
Mach number	$MA = U/A$	Flow speed/Sound speed	Compressible flow
Froude number	$Fr = U^2/gL$	Inertia/gravity	Free surface flow
Weber number	$W_e = \rho U^2 L/\gamma$	Inertia/Surface tension	Free surface flow
Cavitation number (Euler number)	$Ca = (p - p_v)/\rho U^2$	Pressure/Inertia	Cavitation
Prandtl number	$Pr = C_p\mu/k$	Dissipation/conduction	Heat convection
Eckert number	$E_c = U^2/c_pT_o$	Kinetic energy/enthalpy	Dissipation
Specific heat ratio	$\gamma = c_p/c_v$	Enthalpy/internal energy	Compressible flow
Strouhal number	$St = \omega L/U$	Oscillation/mean speed	Oscillating flow
Roughness ratio	ε/L	Wall roughness/Body length	Turbulent, rough walls
Grashof number	$Gr = \beta\Delta TgL^3\rho^2/\mu^2$	Buoyancy/viscosity	Natural convection
Temperature ratio	T_w/T_o	Wall temperature/stream temperature	Heat transfer
Pressure coefficient	$C_p = (p-p_o)/0.5\rho U^2$	Static pressure/dynamic pressure	Aerodynamics, hydrodynamics
Lift coefficient	$C_L = L/0.5\rho U^2A$	Lift force/dynamics force	Aerodynamics, hydrodynamics
Drag coefficient	$C_D = D/0.5\rho U^2A$	Lift force/dynamics force	Aerodynamics, hydrodynamics
Euler number	$E_u = g_c\Delta P/\rho V^2$	Friction head × velocity head	Momentum transfer, fluid frictions
Weber number	$W_e = DV^2\,\rho/g_c\sigma$	Inertial force/surface tension force	Momentum transfer

(b) Now suppose that the water is deep compared to the wave length and the wave height is small compared to the wave length. Also suppose that the waves are long. Try to write the relation you got in part (a) in a simpler form expressing ω just as a function of k.

7.4: Explain the DC breakdown voltage versus electrode distance curve and how it is relevant to dry etching. How is miniaturization of an electrode set equivalent to creating a local vacuum?

7.5: Why is the range of sizes in water-based life much greater than terrestrial life range? Discuss both above and below limits of these ranges.

7.6: Fill in the blank with the correct number for these scaling laws.
(a) Mass scales with a factor of _____.
(b) Stress scales with a factor of _____.
(c) Natural frequency scales with a factor of _____.
(d) Viscous damping scales with a factor of _____.
(e) Coulomb damping scales with a factor _____.
(f) Elastic coulomb damping scales with a factor of _____.
(g) Surface adhesion scales with a factor of _____.
(h) Power scales with a factor of _____.

7.7: How is the number of steps one animal must take per unit distance related to the animal's weight?

7.8: How does velocity scale with size (ignore drag/damping)? (A short two- or three- equation answer—the solution may be surprising.)

7.9: What methods do you recommend to overcome the problem of retention of liquids caused by large surface-to-volume ratios in small biosensors?

7.10: A simple and accurate viscometer can be made from a length of capillary tubing. If the flow rate and pressure drop are measured, and the tube geometry is known, the viscosity can be computed. A test of a certain liquid in a capillary viscometer gave the following data:
- flow rate: 880 mm^3/s
- tube diameter: 500 μm
- tube length: 1 m
- pressure drop: 1.0 MPa

Determine the viscosity of the liquid

7.11: The accepted transition Reynolds number for flow in a circular pipe is Re ~2300. For flow through a 6 cm dia. pipe, at what velocity will this occur at 20°C for (a) airflow and (b) water flow?

7.12: What are the forces that play an important role for (a) very large and (b) very small devices?

7.13: Explain Kleiber's law. What is the generic principle underlying Kleiber's law?

7.14: How do the following forces scale?
(a) Electrostatic force in a constant electric field
(b) Pneumatic and hydraulic forces caused by pressure

7.15: How does the acceleration, transit time, and produced power for each case scale in problem 7.14?

7.16: The required power in a stirring device in a tank is a function of diameter of the device d, number of rotations of the motor per unit time N, density of liquid ρ and viscosity of the liquid η.
(a) Using Buckingham's π theorem, obtain a relation between power P and d, N, ρ, η.
(b) Supposing that the power P is proportional to the square of N, determine by what factor would P be expected to increase if d is doubled.

7.17: A centrifugal pump for pumping the lubricating oil at 15°C rotates at 1000 rpm. For testing this pump, we make a model pump which works with 20°C air. Assuming the diameter of model is 4 times the diameter of the prototype, find the speed at which the model pump should run.

7.18: Complete similarity between a ship model and a full-sized ship requires the same Reynolds and Froude numbers. Suppose that

$$Re = \rho VL/\mu = 11 \times 10^8 \text{ and } Fr^{-1} = gL/V^2 = 33.25$$

Assuming a model 1/100 the size of the ship, can you design an experiment having full similarity?

7.19: In the miniaturization of analytical instruments, scaling laws and breakdown of scaling

laws often determine whether miniaturization will favor sensitivity or not. What will happen to the sensitivity of the following techniques upon miniaturization: (a) the optical path in UV spectrometer; (b) a potentiometric sensor (e.g., a pH sensor); (c) an amperometric sensor (e.g., an oxygen gas sensor); (d) the column in a GC?

7.20: If you miniaturize an absorption-based optical analytical instrument and one based on luminescence, which one scales down more favorably? Explain why.

7. 21: What is the primary assumption of continuum mechanics? Give examples where continuum theory breaks down and how MEMS, in some cases, may take advantage of this breakdown.

7.22: Using dimensional analysis, derive the flow Q of an ideal liquid through an orifice in terms of the density of the liquid ρ, the pressure difference ΔP, and the diameter of the orifice d.

Introduction

An actuator, like a sensor, is a device that converts energy from one form to another (Figure 8.1). In the case of an actuator, one is interested in the ensuing action, while in the case of a sensor what is of interest is the information gained. On the subject of sensor/actuators, we review electrical, magnetic, thermal, chemical, and electrochemical phenomena. From the previous chapter, we know that the dominant physical quantities may change as a function of length scale. In this context, we saw how gravitational (inertial) forces become less effective in the microdomain, whereas van der Waals forces, electrostatic forces, and surface tension forces become dominant. In this chapter we compare different sensor/actuators on the basis of their scaling behavior and other properties,

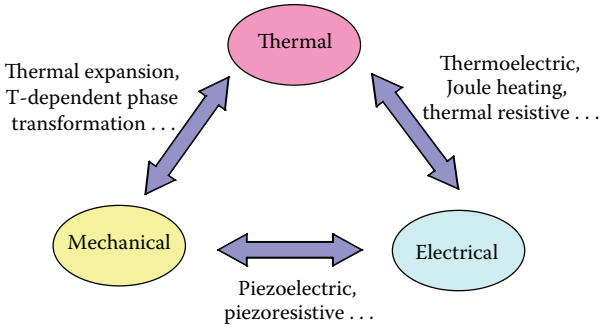

FIGURE 8.1 Energy conversion in sensor and actuator systems.

which, besides size and cost, include dynamic range, displacement (linear or angular), force or torque, response time, and power consumption (see Table 8.1). The results of these comparisons must be seen as guideposts toward a decision only on what actuator to use; yet other considerations (e.g., size of the absolute forces involved, the potential for integration with electronics, materials choice, and manufacturability) may influence the design rules for a particular microsensor or microactuator.

• Manufacturability
• Integration and packaging

1. Sensitivity. The sensitivity of a sensor/actuator is defined in terms of the relationship between input signal and output signal. The sensitivity is, in general, the ratio of a small change in output signal to a small change in input signal. As such, it may be expressed as the derivative of the transfer function* with respect to the input signal. A typical unit is volts/kelvin. A thermometer would have high sensitivity if a small temperature change resulted in a large voltage change.
2. Span or bandwidth. The range of input signals that may be converted to output signals by the sensor/actuator. Signals outside of this range are expected to cause unacceptably large inaccuracy. This span or dynamic range is usually specified by the sensor/actuator supplier as the range over which other performance characteristics described in the data sheets are expected to apply.
3. Accuracy. Generally defined as the largest expected error between actual and ideal output signals. Sometimes this is quoted as a fraction of the full-scale output. For example, a thermometer might be guaranteed to be accurate within 5% of full-scale output (FSO).
4. Hysteresis. Some sensors/actuators do not return to the same output value when the input stimulus is cycled up or down. The width of the expected error in terms of the measured quantity is defined as the hysteresis. A typical unit is percentage of full-scale output.
5. Nonlinearity (often called *linearity*). The maximum deviation from a linear transfer function over the specified dynamic range. There are several measures of this error. The most common compares the actual transfer function with the "best straight line," which lies midway between the two parallel lines that encompass the entire transfer function over the specified dynamic

* The functional relationship between input signal and output signal. Usually, this function is represented as a graph showing the relationship between the input and output signal, and the details of this relationship may constitute a complete description of the sensor/actuator characteristics. For expensive sensors/actuators which are individually calibrated, this might take the form of a certified calibration curve.

range of the device. This choice of comparison method is popular because it makes most sensors/actuators look their best.

6. Noise. All sensors/actuators produce some output noise in addition to the output signal. This noise limits the performance of the system. Noise is generally distributed across the frequency spectrum. Many common noise sources produce a white noise distribution, which is to say that the spectral noise density is the same at all frequencies. Since there is an inverse relationship between the bandwidth and measurement time, it can be said that the noise decreases with the square root of the measurement time.
7. Resolution. The resolution of a sensor/actuator is defined as the minimum detectable signal fluctuation. Since fluctuations are temporal phenomena, there is some relationship between the timescale for the fluctuation and the minimum detectable amplitude. Therefore, the definition of resolution must include some information about the nature of the measurement being carried out.
8. Dynamic range or frequency response. All sensors/actuators have finite response times to an instantaneous change in input signal. In addition, many sensors have decay times, which would represent the time after a step change in physical signal for the sensor output to decay to its original value. The reciprocal of these times correspond to the upper and lower cutoff frequencies, respectively. The bandwidth of a sensor is the frequency range between these two frequencies.

Jargon from different science disciplines and various application fields often makes interdisciplinary microelectromechanical system (MEMS) and nanoelectromechanical system (NEMS) discussions challenging. A useful scheme for standardizing the classification of miniaturized sensors and actuators would make communication between researchers from different disciplines (manufacturers, immunologists, mechanical engineers, market researchers, etc.) easier. Several such attempts have been made in that direction. We state our favored approach here. White[1] describes a classification scheme derived from a Hitachi Research Laboratory communication. He distinguishes ten different domains or fields:

1. Acoustic
2. Biological
3. Chemical
4. Electrical
5. Magnetic
6. Mechanical
7. Optical
8. Radiant
9. Thermal
10. Other

Middlehoek and Audet[2] follow Lion[3] and contract this list to six domains:

1. Radiant
2. Mechanical
3. Thermal
4. Electrical
5. Magnetic
6. Chemical

For simplicity, we adopt the latter list here. Based on Gopel et al.[4] and Habekotte,[5] Table 8.2 exemplifies sensing/actuating principles in these six signal domains. Since the listed energy domains can be energy input as well as energy output, a 6×6 matrix results. The table also presents an example device in each field. We may have a mechanical sensor/actuator converting mechanical energy into thermal energy (i.e., a thermomechanical device such as a friction calorimeter), but also a thermal sensor/actuator converting thermal energy into mechanical energy (e.g., a mechanothermal sensor such as a bimetallic strip).

In the literature, no logic seems to be applied concerning the use of "thermo-optical" or "opto-thermal." Middlehoek and Audet[2] further distinguish between self-generating and modulating sensors/actuators. A device based on a modulating principle requires an auxiliary energy source. An example of a modulating sensor is a fiber-optic magnetic-field sensor in which a magnetostrictive jacket is used to convert a magnetic field into an induced strain in the optical fiber. A sensor/actuator based on a self-generating principle does not require an auxiliary energy source (e.g., a thermocouple in

Table 8.2 Example of Transduction Principles

Input (Primary Signal)	Output (Secondary Signal)					
	Mechanical (Mechano-)	Thermal (Thermo-)	Electrical (Electro-)	Magnetic (Magneto-)	Radiant (Photo- or Radio-)	Chemical (Chemo-)
Mechanical	Acoustics, fluidics	Friction calorimeter, cooling effects	Piezoelectricity, piezoresistivity	Piezomagnetic effect	Photoelasticity, Doppler effect	Motor proteins
Thermal	Thermal expansion, bimetallic strip		Pyroelectricity, Seebeck effect		Radiant emission	Reaction activation
Electrical	Piezoelectricity, electrometer	Joule heating, Peltier effect	Langmuir probe	Biot-Savart's law	Electroluminescence, Kerr effect	Electrolysis
Magnetic	Magnetostriction, magnetometer	Thermomagnetic	Magnetoresistance		Faraday effect, Cotton-Moulton effect	
Radiant	Radiation pressure	Thermopile, bolometer	Photoelectric, dember		Optical bistability	Photoreactions
Chemical	Hygrometer	Calorimeter, thermal conductivity	Amperometry, flame ionization, Volta effect	Nuclear magnetic resonance	Chemiluminescence	

which a change in temperature directly results in an electrical signal that can be measured). The difference between the two is illustrated in Figure 8.2.[6] Since the modulating sensor needs another energy input, one also refers to such sensors as *passive*, whereas the self-generating sensors are *active*.

Irrespective of the fact of dealing with a small sensor, an actuator, or a microsystem, we can always describe the function of the miniaturized device in terms of the matrix in Table 8.2.

There are many reasons for wanting to miniaturize systems, actuators, power sources, sensors, and components. In some cases, the reason is favorable scaling—for example, smaller devices tend to be faster and consume less power. Scaling may also disfavor miniaturization, as often happens with actuators

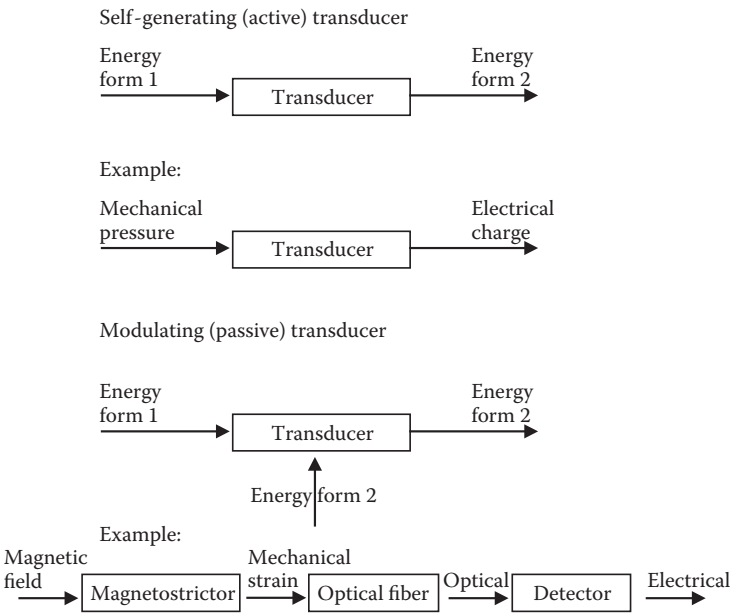

FIGURE 8.2 Comparison of self-generating (active) transducer and modulating (passive) transducer; the piezoelectric sensor represents a self-generating transducer, and the fiber optic magnetic field sensor represents a modulating transducer. (After National Research Council.)

and power sources; smaller actuators exert less force, and smaller power sources harness less power.

Finally, actuator materials are often called *smart materials*, which refers to materials that undergo precise transformations through physical interactions. Examples include piezoelectric materials, shape memory alloys (SMAs), conductive polymers, electrochromic materials, smart gels, rheological materials, biomaterials, electrostrictive materials, magnetostrictive materials, and electrorheological fluids. All these materials have potential uses in actuators that control chatter in precision machine tools, improved robotic parts that move faster and with greater accuracy, smaller microelectronic circuits in machines ranging from computers to photolithography printers, and health-monitoring fibers for bridges, buildings, and utility poles.

Electric Actuators

Under electric actuators, we consider all actuators that involve electrical fields (DC or AC); this includes, foremost, electrostatic and piezoelectric actuators, which we study in the most detail. Besides electrostatic and piezoelectric devices, we consider dielectric induction effects on particles in liquids and on liquids themselves, where one speaks about dielectrophoresis (covered in Volume I, Chapter 6) and electrohydrodynamics (EHD), respectively. Finally, under electric actuators, we also explain how electrostrictive materials, pyroelectrics, thermoelectrics, electrets, and electrorheological fluids work.

Electrostatics

Introduction

In electrostatic sensors and actuators, electrically charged materials are used. These materials can exert an attractive force on oppositely charged objects or a repulsive force on similarly charged ones. We start by introducing the simplest of electrostatic actuators, namely a parallel plate capacitor. This is followed by an introduction to electrical and mechanical equivalent circuits and the correspondence of their respective elements. This gives us the background for considering the dynamic behavior of a parallel plate capacitor. We then further describe the two most important characteristics of electrostatic actuators, i.e., their natural frequency and quality factor. We also introduce some other electrostatic actuators, such as wobble motors and switches, and compare them with other types of actuators. We finish this section with a summary about electrostatic actuators and a more general approach to modeling them.

Parallel Plate Capacitor Based Actuators

A parallel plate capacitor, as shown in Figure 8.3, is an example of a simple electrostatic actuator. We calculate the stored energy density in a capacitor with plate area A and distance between the plates d as follows:

$$U = \frac{1}{2}\varepsilon_0\varepsilon_r\frac{A}{d}V^2 = \frac{1}{2}\varepsilon(Ad)E^2 \qquad (8.1)$$

(see also Equation 7.34, with $\varepsilon = \varepsilon_r\varepsilon_0$ wv = A and $V_b = V$).

The stored energy density is then obtained by dividing U from Equation 8.1 by the volume of the capacitor (Ad), or:

$$U' = \frac{1}{2}\varepsilon E^2 = \frac{1}{2}\mathbf{D}\cdot\mathbf{E} \qquad (8.2)$$

where we bolded D and E to remind the reader that we are dealing with vectors here (see also Equation 7.36, modified to describe all fields, E, not just the breakdown field, E_b, and with $\varepsilon = \varepsilon_r\varepsilon_0$):

The electrostatic surface force is given by the following equation (a generalization of Equation 7.37):

$$F = -\nabla U \qquad (8.3)$$

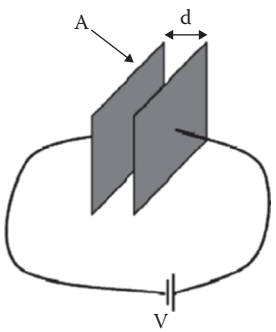

FIGURE 8.3 Parallel plate capacitor.

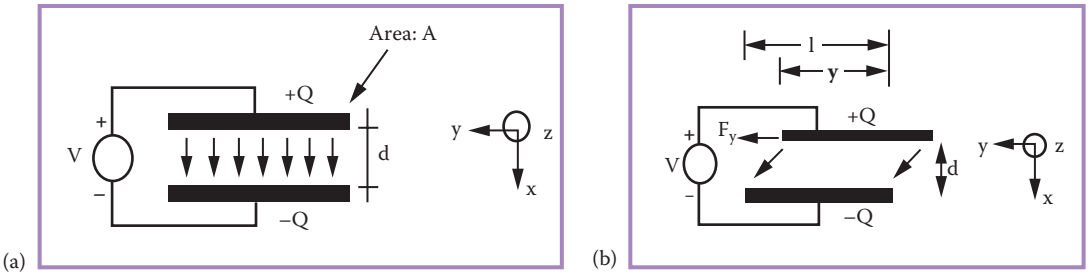

FIGURE 8.4 Vertical-driven (a) and parallel-driven (b) parallel plate capacitor actuators.

Let us now consider parallel- and vertical-driven parallel plate capacitor actuators, as depicted in Figure 8.4.

If the two plates of the parallel capacitor in a microactuator are displaced perpendicular to each other (d changes along the x-direction), the force of attraction in the x-direction, based on Equations 8.1 (with $\varepsilon_r = 1$) and 8.3, is given as follows:

$$F_x = -\frac{\partial U}{\partial x} = \frac{1}{2}\frac{\varepsilon_0 A}{x^2}V^2 \qquad (8.4)$$

Vertically driven resonant microstructures operate in this mode (see Figure 8.5a). Vibration in the x-direction in this case is excited electrostatically, and motion is detected electrostatically as well; that is, by sensing the change in capacitance.[7]

In Chapter 7, we saw that the electrostatic force, F_x, for a constant field, scales as l^2, since:

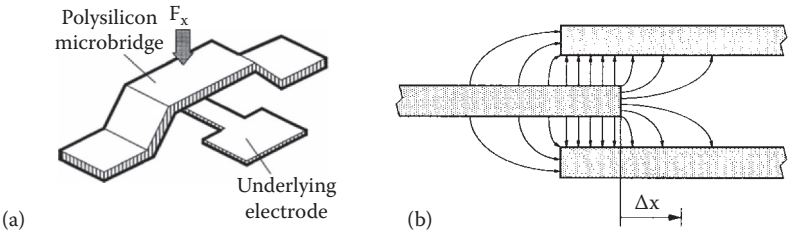
$$F_x = -\frac{\partial U}{\partial x} = \frac{V^2}{2}\frac{\partial C}{\partial x} = \frac{1^3}{1^1} = 1^2 \qquad (7.37)$$

where V is the applied voltage. This l^2 scaling of the electrostatic force often constitutes an advantage compared with other forces when miniaturizing an actuator. For example, mass and hence inertial forces scale as l^3, and from Chapter 7, we know that the lower the exponent of l, the more important the force becomes in the microdomain (see also below and Figure 8.8).

A large displacement in a micromachined electrostatic actuator element can best be achieved if one plate (the actuator) moves parallel to the other capacitor plate rather than perpendicular to it (see Figures 8.4b and 8.5b). For a parallel movement of the plates (in the y-direction or z-direction), Equations 8.1 and 8.3 result in a force of attraction parallel to the plates, which for the y-direction is given by the following equation:

$$F_y = \frac{1}{2}\frac{\varepsilon_0 z}{d}V^2 \qquad (8.5)$$

Notice that the force is constant for a y directional translation, i.e., the force is scale-independent in



Vertical resonator	Horizontal resonator
+ Parallel plates—good drive and sense	− Fringing fields—weak drive and sense
− Amplitude limited to less than 1/3 of gap	+ Larger vibration amplitudes
− Squeeze-film damping in air	+ Couette flow—damping less dissipative
− Difficult to couple mechanically	+ Enables a variety of mechanical coupling

Electrostatic comb drive for resonant sensor and actuator applications. PhD thesis, University of California, Berkeley.[7]) (c) Summary of the pros and cons of vertical and lateral resonators, from a lecture by Dr. Bill Tang (University of California, Irvine).

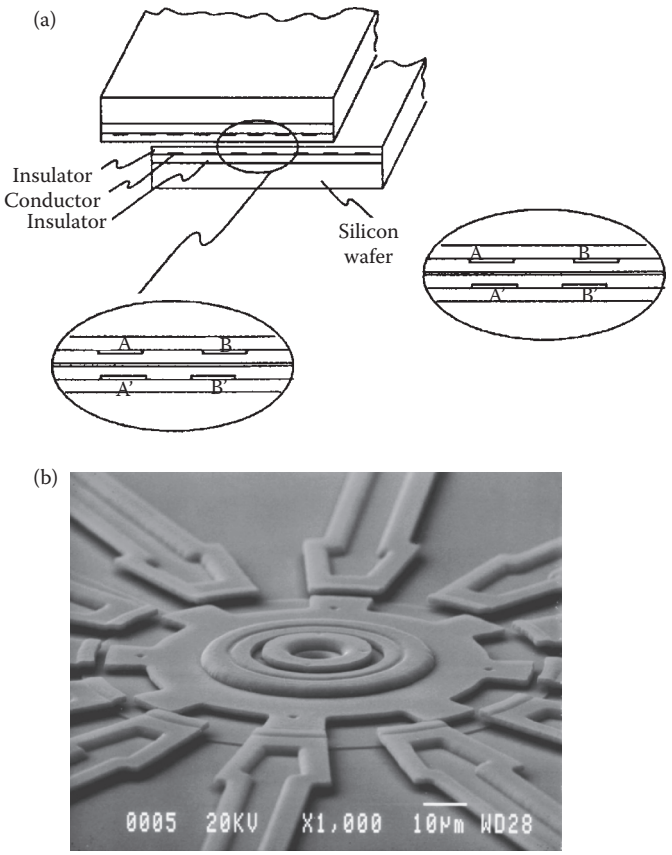

FIGURE 8.6 (a) Linear electrostatic motor: when a voltage is applied to the misaligned plates A-A', a force is exerted, which aligns plates A-A'. Now, plates B-B' are misaligned and in a position to be activated to cause a motion. (After Trimmer, W. S. N., and K. J. Gabriel. 1987. Design considerations for a practical electrostatic micromotor. *Sensors Actuators* 11:189.[11]) (b) Rotational electrostatic motor: scanning electron microscope micrograph of a polysilicon 12:8 salient pole micromotor. The rotor sits atop a 0.5-mm-thick layer of polysilicon that acts as an electrostatic shield. Rotor, hub, and stators are formed from 1.5-mm-thick polysilicon. A 2.0-mm-thick polysilicon disk is attached to the rotor. In turn, the hub overlaps this disk to pin the rotor onto the substrate. (Courtesy of D. Koester, MCNC-MEMS Technology Applications Center.) The first polysilicon motors were made at University of California, Berkeley (Fan, Tai, and Muller), Massachusetts Institute of Technology, and AT&T. Typical starting voltages were >100 V, and operating voltages were >50 V.

that direction ($F \sim l^0V^2$). In this case, the force parallel to the plates wants to realign the plates. This is exploited, for example, in laterally driven linear and rotary electrostatic motors or side-drive motors (see Figure 8.6a and b). The lateral force remains constant during the movement as long as the fringing fields can be neglected (see Figure 8.5b). Besides longer strokes, driving and sensing of planar microstructures parallel to the substrate have two other major advantages over a vertical movement of the plates: the forces change linearly with distance (see Equation 8.5), and dissipative squeeze damping is avoided.[8–10] The latter is related to the magnitude of the viscous losses when moving structures displace fluids (usually air) from small separator gaps. Losses are larger for vertical displacement of fluids, leading to squeeze-film damping and a resultant low-quality factor (Q) (see below) for resonating elements. Couette flow (see Volume I, Chapter 6, on fluidics) in the gap between the structure and the substrate for lateral motion of the actuator is much less dissipative than squeeze-film damping, and higher Q resonators are obtained. Figure 8.5c summarizes the pros and cons of vertical and lateral resonators.

Lateral electrostatic actuation is very important in linear resonators with comb-like structures, such as the device shown in the header of this chapter. These comb drives are used, for example, in accelerometers [see the Analog Devices' ADXL-50 accelerometer, with a surface micromachined capacitive sensor (center), on-chip excitation, self-test, and signal-conditioning circuitry in Volume II, Figure 7.92]. By applying a voltage, a movable shuttle moves toward a fixed part (Volume II, Figures 7.76 and 7.93). For a rectangular design of the resonator beams, the force and the microactuator displacement is proportional to the ratio of structure height, T, versus separation gap, d, that is, the achievable aspect ratio and the number of fingers, N:

$$F = \frac{1}{2}\frac{\varepsilon_0 TN}{d}V^2 \qquad (8.6)$$

An efficient comb drive with a large F can thus be achieved by designing many high comb fingers with narrow gaps. In polysilicon surface micromachining, the thickness, T, is typically limited to about 2–3 µm, whereas with LIGA or pseudo-LIGA methods, a thickness of several hundred micrometers is possible (Volume II, Chapter 10). Clearly, the latter machining methods have the potential to produce the strongest electrostatic actuators. Mohr et al. further showed that by making the comb fingers trapezoidal in shape, the maximum displacement of the interdigitated fingers can be further increased,

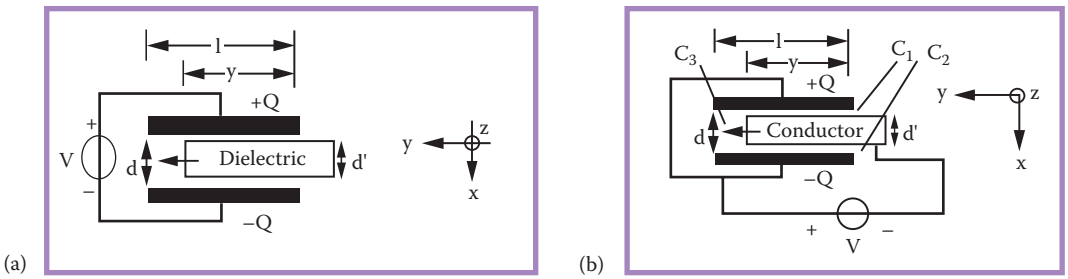

FIGURE 8.7 Dielectric (*a*) or metallic (*b*) slabs of material are moved into the gap of a parallel plate capacitor.

as smaller capacitor gaps are possible this way.[12] For a more rigorous mathematical derivation of Equation 8.6, we refer to the finite-element simulation of comb drives by Tang.[7]

When a dielectric or a metallic slab is moved between the two plates of a parallel plate capacitor as shown in Figure 8.7, Equation 8.5 must be modified as follows:

$$F_y = \frac{1}{2}\frac{(\varepsilon_d - \varepsilon_0)z}{d'}V^2 \tag{8.7}$$

for a dielectric slab of thickness d' and dielectric constant ε_d (Figure 8.7a). For a metal slab of thickness d' inserted in the capacitor gap, one derives the following equation (Figure 8.7b):

$$F_y = \frac{1}{2}\frac{\varepsilon_0 z d'}{d(d-d')}V^2 \tag{8.8}$$

It is important to be able to evaluate the relative importance of different competing forces as one downscales an actuator. In Figure 4.39, we compare gravity, van der Waals, electrostatic, and surface tension forces that are involved when picking and placing small objects during assembly. From this graph it is clear that surface forces become more dominant as structures become smaller. Here we detail the relative importance of gravitational versus electrostatic forces for deciding upon an actuator mechanism in the microworld. In Figure 8.8, we consider competing gravitational and electrostatic forces working on a cube of material with length L, density ρ, and charge q. The gravitational force, F_g, working on the cube is given as follows:

$$F_g = g\rho V = g\rho L^3 \tag{8.9}$$

Based on Equation 8.4, with $\sigma = q/A$ ($A = L^2$) and $AE = q/\varepsilon$, the electrostatic force F_e ($\equiv F_x$) working upon the cube is given by the following equation:

$$F_e = \frac{1}{2}\varepsilon AE^2 = \frac{\sigma^2}{2\varepsilon}L^2 \tag{8.10}$$

Hence, when:

$$L < \frac{\sigma^2}{2g\rho\varepsilon} \tag{8.11}$$

electrostatics dominates (the intersection of the red and blue line in Figure 8.8 occurs at $F_g = F_e$). The electrostatic force, as we learn in Chapter 7, gains over inertial forces as the size of the system is decreased: the electrostatic force, with the lowest exponent in l, becomes the dominant force in the microdomain (surface force is l^2 vs. l^3 for gravitation). A decrease in size by a factor of 10 leads to a decrease of the inertial forces by a factor of 1000, whereas the electrostatic force decreases by a factor of only 100. It is thus not hard to exert rapid accelerations in microsystems with the aid of electrical fields.

Correspondence between Electrical and Mechanical Circuits

In this section we briefly introduce the correspondence between electrical and mechanical circuits.

For modeling of electrostatic actuators as shown in Figure 8.7, it is useful to make abstractions of the electrical and mechanical system elements as illustrated in Table 8.3. In this table we list the correspondence between the parameters in electrical and mechanical circuits. In the inset in this table, the gap of the electrostatic actuator is marked with the letter *g*, not to be confused with the gravitational constant. Movement of the electrostatically actuated structure with spring constant *k* is in the *z*-direction.

We will come back to modeling electrostatic actuators at the end of "Electrostatics."

Dynamics of Electrostatic Actuators

Dynamics is the branch of classical mechanics that is concerned with the motion of bodies. Here we consider the dynamics of an electrostatic actuator. In the electrostatic actuator shown in Figure 8.9, the electrostatic force, F_e (V) (see Equation 8.4, with x replaced by g, the instantaneous gap spacing, and ε_0 replaced by ε) works against a mechanical restraint $F_s = kz$. The latter is Hooke's law, with k the spring constant and z the displacement of the movable plate, $z = g - g_0$, with g_0 the initial gap spacing, i.e., the gap without applied voltage.

A stable equilibrium results when the electrostatic and mechanical force are equal in absolute magnitude but opposite in sign, i.e., $F_e = -F_s$, or as follows:

$$F_e = \frac{1}{2}\frac{\varepsilon A V^2}{g^2} = -kz = k(g_0 - g) \qquad (8.12)$$

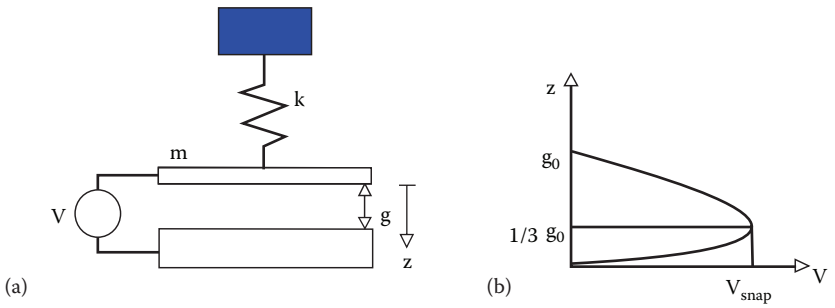

FIGURE 8.9 (a) Schematic of an electrostatic actuator. (b) At the snap voltage, V_{snap}, there is an electrostatic instability or a pull-in of the electrostatic actuator, where g_0 is the initial gap spacing and the snap voltage occurs at 1/3 of the initial gap spacing.

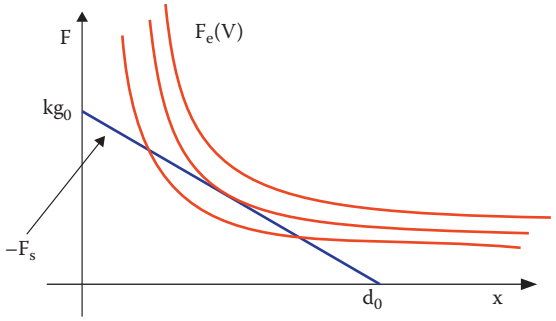

FIGURE 8.10 Positioning of a capacitor plate. The blue line is simply Hooke's law, and the three red lines are the electrostatic force for three different voltages.

This relationship is illustrated in Figure 8.10 for three different voltage values. Notice that the blue line (Hooke's law) intersects the lowest red F_e (V)-curve (electrical force) at two points and touches the next red F_e (V)-curve at only one point. These intersection points and the contact point are now analyzed further.

From Figure 8.10, we recognize that at $g = g_0$ ($z = 0$), when there is no voltage applied, $F_s = 0$. When the electrostatic actuator pull-in has shunted the capacitor plates, the gap $g = 0$ ($z = -g_0$), and the force $F_s = kg_0$.

On the basis of Equation 8.12, we derive the following voltage dependence on z:

$$V = \sqrt{\frac{2kz}{\varepsilon A}}(g_0 - z) \tag{8.13}$$

This is plotted in Figure 8.9b. When the applied voltage, V, is larger than V_{snap} (the snap or pull-in voltage), an unstable situation results (the system loses equilibrium) and the capacitor plates snap together. Let us analyze the conditions for this electrostatic instability in a bit more detail. An equilibrium point is unstable if in the presence of a small perturbation the net force does not tend to return the system back to the equilibrium position. The net force is the sum of the electrostatic and mechanical force, $F_{net} = F_e + F_s$, or, from Equation 8.12:

$$F_{net} = -\frac{\varepsilon AV^2}{2g^2} + k(g_0 - g) \tag{8.14}$$

For a stable equilibrium point, the variation of the net force (δF_{net}) should be of the opposite sign to the perturbation (δg), i.e., $\delta F_{net}/\delta g < 0$. We calculate ΔF_{net} as follows:

$$\delta F_{net} = \frac{\partial F_{net}}{\partial g}\bigg|_V \delta g = \left(\frac{\varepsilon AV^2}{g^3} - k\right)\delta g \tag{8.15}$$

When $\delta g > 0$, the system becomes unstable if $\delta F_{net} > 0$, and the system becomes stable if $\delta F_{net} < 0$, or for a stable equilibrium, one must have the following condition:

$$k > \frac{\varepsilon AV^2}{g^3} \tag{8.16}$$

At the electrostatic instability voltage, pull-in voltage or snap voltage, V_{snap} (the peak of the curve in Figure 8.9b: $\delta V/\delta z = 0$), the net force $F_{net} = 0$, and one obtains the following:

$$k = -\frac{\varepsilon AV_{snap}^2}{g_{snap}^3} \tag{8.17}$$

and:

$$F_{net} = -\frac{kg_{snap}}{2} + k(g_0 - g_{snap}) = 0 \tag{8.18}$$

From Equation 8.18, we derive for the value of g_{snap}:

$$g_{snap} = \frac{2}{3}g_0 \tag{8.19}$$

The value for V_{snap}, the electrostatic instability or snap voltage, is then as follows:

$$V_{snap} = \sqrt{\frac{8kg_0^3}{27\varepsilon A}} \tag{8.20}$$

Representing a normalized displacement as:

$$\zeta = \frac{z}{g_0} = 1 - \frac{g}{g_0} \tag{8.21}$$

And a normalized voltage as:

$$\nu = \frac{V}{V_{snap}} \tag{8.22}$$

The equilibrium condition can be represented as:

$$\frac{4}{27}\frac{\nu^2}{(1-\zeta)^2} = \zeta \tag{8.23}$$

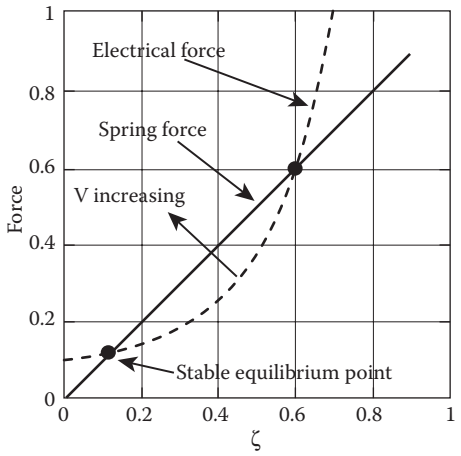

FIGURE 8.11 Force, *F*, as a function of ζ (with ν = 0.8). The spring force is marked by a solid line and the electrical force by an arched line (see also Figure 8.10).

The two intersection points merge when $\zeta = 1/3$ ($g_{snap} = 2/3g_0$) and $\nu = 1$ ($V = V_{snap}$), and this point corresponds to the pull-in point. As shown in Figure 8.10, this is the point where the blue line just touches the red curve. In Figure 8.11, we plot the force, *F*, as a function of ζ (with ν = 0.8). The spring force is marked by a solid line and the electrical force by an arched one.

Fundamental Frequency and Quality Factor of Electrostatic Resonators

Introduction

Two very important characteristics for electrostatic actuators are the fundamental frequency and the quality factor of the moving parts in these systems. The fundamental frequency of a resonating part is the frequency at which a free system vibrates. There are two different common definitions of the *Q* of a resonator. One is via the energy storage, where the *Q* is given as 2π times the ratio of the stored energy to the energy dissipated per oscillation cycle, or equivalently the ratio of the stored energy to the energy dissipated per radian of the oscillation. The other definition is via the resonance bandwidth in which the *Q* is the ratio of the resonance frequency f_0 and the full width at half-maximum (FWHM) bandwidth, Δf, of the resonance. Both definitions are equivalent only in the limit of weakly damped oscillations, i.e., for high *Q* values.

Fundamental Frequency

The fundamental or natural frequency, f_0, of a simple spring-mass system resonator is given by:

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{k}{m}} \tag{8.24}$$

and:

$$\omega_0 = 2\pi f_0 = \sqrt{\frac{k}{m}} \tag{8.25}$$

with *k* the spring constant (defined as load/deflection), *m* the mass, and ω_0 the natural circular frequency. The spring constant *k* in the two preceding equations scales as *l*, and *m* scales as l^3; it follows that the resonance frequency scales as $f_0 \sim l^{-1}$, confirming that the smaller the resonator the higher its resonant frequency.

For a more complicated resonator, of the type shown in the header of this chapter, the same fundamental equation holds but with the spring constant *k* replaced by *K*, that is, the effective spring constant (also stiffness constant or stiffness matrix), and *m* replaced by *M*, that is, the effective mass or mass matrix of the structure. The stiffness matrix varies with geometry as well as with the induced stresses.

With reference to Table 8.3, we recognize that just as a spring-mass combination has a natural (resonant) frequency determined by the stiffness of the spring and the magnitude of the mass, so too do the values of an inductor and capacitor determine the natural oscillating frequency of an electrical inductance-capacitance (LC) circuit. The larger the inductance, the longer it takes a given moving charge to set up a magnetic field. Since a given charge produces only a small voltage across a large capacitor, the larger the capacitance the longer it will take to charge and discharge that capacitor. The natural oscillating frequency of an LC circuit is given by the following expressions:

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{1}{LC}} \tag{8.26}$$

and:

$$\omega_0 = 2\pi f_0 = \sqrt{\frac{1}{LC}} \tag{8.27}$$

Quality Factor

The Q of a resonator, in one of the two prevailing definitions (see introduction above), is given as the ratio of stored over lost energy in one cycle.

$$Q = 2\pi \frac{E}{\Delta E} = 2\pi \frac{\tau}{T} = \tau\omega_0 \tag{8.28}$$

For a mechanical system as sketched in the inset in Table 8.3, the mechanical quality factor is then calculated as follows:

$$Q = \tau\omega_0 = \frac{m}{b}\omega_0 = \frac{\sqrt{km}}{b} \tag{8.29}$$

with b the damping in the system. From the discussion in the introduction above, m and k should be replaced by M and K for more complex resonator structures.

Analogously, for an electrical system, the quality factor is given by the following:

$$Q = \tau\omega_0 = \frac{L}{R}\omega_0 = \frac{1}{R}\sqrt{\frac{L}{C}} \tag{8.30}$$

with L the inductance and C the capacitance (see Table 8.3).

Typical mechanical quality factors for laterally driven polysilicon resonant microstructures (see figure in the header of this chapter) are about 100 or less.[8] A poly-SiC lateral resonator, a material with a high Young's modules and thus a high k, at $<10^{-5}$ Torr, has been micromachined and features Q values >100,000.[13] In a good vacuum, b in Equation 8.29 becomes very small, further improving the factor Q. For NEMS devices, Qs attained today in moderate vacuum are in the range of 10^3 to 10^5. This greatly exceeds typical Qs from electrical resonators. A high Q is linked to small internal dissipation ($D = 1/Q$), imparting, in turn, low operating power levels and high attainable force sensitivity to nanodevices.[14]

Merits of Electrostatic Devices

To analyze the merits of electrostatic actuators, we start by deriving the maximum energy density one can store in such an actuator. In Chapter 7, on scaling, we saw that the maximum electrostatic energy density, U'_m (in J/m^3), between the capacitor plates of an electrostatic actuator is obtained by dividing the maximum potential energy, U_m, by the volume, V_0, of the capacitor gap, $V_0 = w \times v \times d$ (see Figure 7.11):

$$U'_m = \frac{\varepsilon_r \varepsilon_0 E_b^2}{2} \tag{7.36}$$

where E_b represents the highest attainable electric field in the actuator, i.e., the electric breakdown field strength. For an air capacitor, E_b is limited to approximately 3×10^6 Vm^{-1} by the electrical breakdown of air. Thus, the stored energy for an air capacitor is about 40 Jm^{-3}. Electrostatics is a surface force, and the surface force density, F', is given by the following (derivative of Equation 8.4):

$$F' = \frac{\partial F}{\partial A} = \frac{\varepsilon_r \varepsilon_0 E^2}{2} \tag{8.31}$$

where A stands for the surface area. The surface force density equals the energy density in the field. Hence, one wants to use the maximum field possible for the largest possible force. In Chapter 7, we saw that this force scales as l^2, which is favorable in the microdomain where forces with the lowest exponent win out (e.g., electrostatics with l^2 win out over the l^4 scaling of magnetic actuators).

Our reasoning so far involves isotropic electrical fields only. In Chapter 7 we saw that besides favorable scaling, the Paschen effect represents another advantage for microelectrostatic systems. Working on the left side of the Paschen curve (see Figure 7.12) renders very high-field operation possible for a wide variety of electrostatic microdevices without incurring catastrophic sparking. Examples include the electrostatic motors illustrated in Figure 8.6b, the electrostatic switch in Figure 8.13, and the author's volcano ionization sources presented in Example 7.1 at the end of Chapter 7 (Figure 7.14). The field in the nonisotropic Paschen regime scales more nearly as $l^{-1/2}$, whereas the force scales as l^1. With a factor of 10 reduction in size, the inertial force still decreases by a factor of 1000, but the electrostatic force decreases only by a factor of 10. Acceleration and transit times are also higher than for the isotropic system. Superficially, this seems to put magnetic motors, based on volume forces, at a disadvantage compared with electrostatic micromotors. We shall see, however, that this is not the end of the story. For example, magnetic field energy can be made two

orders of magnitude greater than the best one can achieve with electrostatic fields and small air gaps in air or vacuum.[15]

We are interested in using electrostatic force in all types of actuators: not only simple parallel plate capacitors but also linear and rotational motors. As we saw earlier, the force, *F*, is the negative spatial derivative of the energy, *U*, in the system (Equation 8.3). In the case we move the plate of a capacitor with respect to another plate, the electric force will be the spatial derivative, in that direction, of the stored energy *U*. The translational movement of one plate with respect to the other in a linear motor moving in the *x*-direction leads to a force, F_x, as follows:

$$F_x = -\frac{\partial U}{\partial x} = \frac{V^2}{2}\frac{\partial C}{\partial x} = \frac{1^3}{1^1} = 1^2 \qquad (7.37)$$

where *V* is the applied voltage. The electrostatic force for a constant field is thus found to scale as l^2. This is often an advantage, because the mass and, hence, inertial forces scale as l^3. The latter point was clearly illustrated in Figure 8.8.

From Equation 7.37 translational motor action is associated with a change in the capacitance: an increase in capacitance for a motor, a decrease in capacitance for a generator. For a rotational motor a rotational force, F_r, by analogy to Equation 7.37 is defined as follows:

$$F_r = -\frac{\partial U}{\partial \theta} \qquad (8.32)$$

where $\partial\theta$ is the differential angular displacement in radians. From Equations 7.37 and 8.32, F_r can be expressed in terms of the change in capacitance.

$$F_r = -\frac{V^2}{2}\frac{\partial C}{\partial \theta} = -\frac{q^2}{2C^2}\frac{\partial C}{\partial \theta} \qquad (8.33)$$

The second expression on the right is obtained by introducing the relation $V = qC^{-1}$, where *q* is the total charge on the capacitor plates. Detailed calculations of the capacitance of electrostatic motors/generators can be found in Mahadevan[16,17] and in Kumar et al.[18] Torque of a rotational motor is given by the following:

$$T = r \times F_r \qquad (8.34)$$

With *r* the radius and F_r perpendicular, Equation 8.34 simply becomes $T = r \cdot F_r$. The power, *P*, generated by the motor can easily be calculated from the torque as follows:

$$P = T\omega = T2\pi f \qquad (8.35)$$

where ω represents the angular frequency and *f* the frequency at which the motor rotates. From Equation 8.35, one would expect that as electrostatic motors decrease, the inherent increase in frequency could help to offset the decrease in torque. However, static and dynamic frictional forces (surface forces!) come into play and are a major barrier. Despite these problems, surface-micromachined electrostatic motors of the type shown in Figure 8.6b, with rotational speeds of 15,000 rpm and continuous operation for over a week, have proven to be possible at voltages below 300 V.[19] Friction-reduction methods include deposition of a silicon nitride sliding surface; electrostatic, magnetic, or other types of levitation; and replacing sliding contacts with rolling contacts in wobble or harmonic motors.[20,21]

In harmonic motors, the rotor rolls on the inside of the stator without slipping and rotates slightly in the process (Figure 8.12). It is this slight rotation

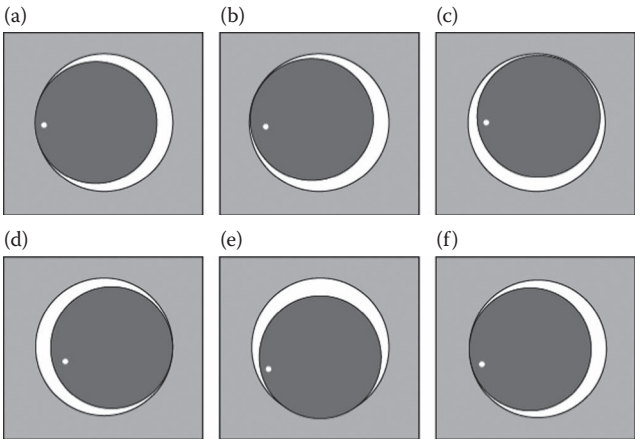

FIGURE 8.12 Wobble or harmonic motors. (a) The rotor is touching the edge of the hole to the left. The white dot marks a point on the rotor; (b)–(f) show the rotor as it progressively rolls around the hole in a clockwise manner. Note the position of the white dot in (f) after one rotation. The rotor has twisted about its axis slightly in a counterclockwise direction. As the rotor rolls repeatedly around the hole, the twisting motion produces an output torque.

of the rotor that produces the output motion of the motor. Applying voltages between the rotor and electrodes in the stator hole electrostatically drives the rotor. Each of the rotations of the rotor about the stator hole produces another small twist of the rotor axis, producing a beneficial gear reduction. Advantages of this type of motor are the rolling motion, which avoids sliding friction, the closeness of the rotor and stator, enabling a higher electrostatic energy density, and the gear reduction, producing a large torque. Harmonic motors do not scale up well, however, and Trimmer compares large wobble motors to an unbalanced washing machine.[22] In the microdomain, inertial effects decrease, and these unbalanced forces are insignificant for microharmonic motors.

To drive a load several hundred micrometers in thickness and width and several millimeters in diameter, the required torque of a motor is of the order of 10^{-5} Nm. However, the torque generated with a typical surface-micromachined electrostatic motor, 100–150 µm in diameter and with an air gap of about 2 µm, is only in the nano-newton-meter or pico-newton-meter range (see Figure 8.6b).[21] Calculation for an outer rotor, surface-micromachined wobble motor,* with copper electroplated structural elements, indicates that to achieve a torque of 10^{-4} to 10^{-5} Nm, the stator radius must be a few millimeters, and the thickness needs to be of the order of 10 µm.[24] As frequently observed, actuators do not scale advantageously in the microdomain. Torque is a volume effect, and small-size devices have a limited range of force available for actuation. In view of this recognition, perhaps an excessive amount of research has gone into surface-micromachined electrostatic motors. These flat surface micromachined micromotors could still find a use, though, as shutters for charged particle or photon beams, memory writing/reading devices, masks with movable parts, etc.—in other words for applications in which the required forces are minimal. Below, we will compare electrostatic motors with the more complicated and typically larger micromachined magnetic motors that, it appears, can perform a broader range of work more readily.

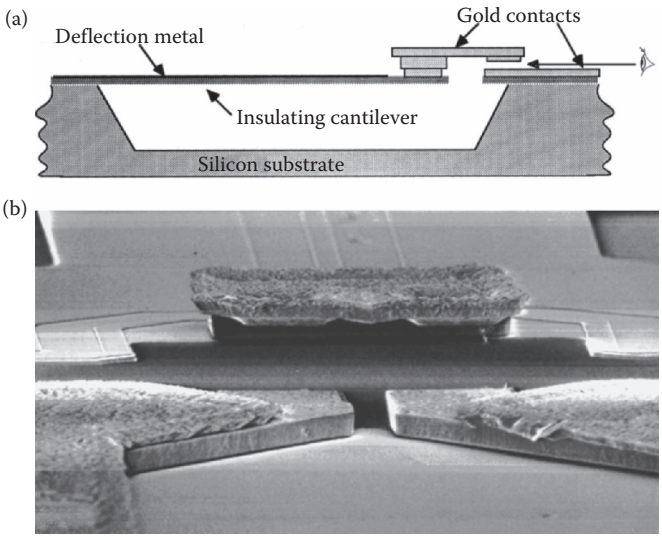

FIGURE 8.13 Electrostatic microswitch. (a) Schematic; (b) Scanning electron microscope micrograph, looking straight into the opened contact. Switch built by the author's research group.

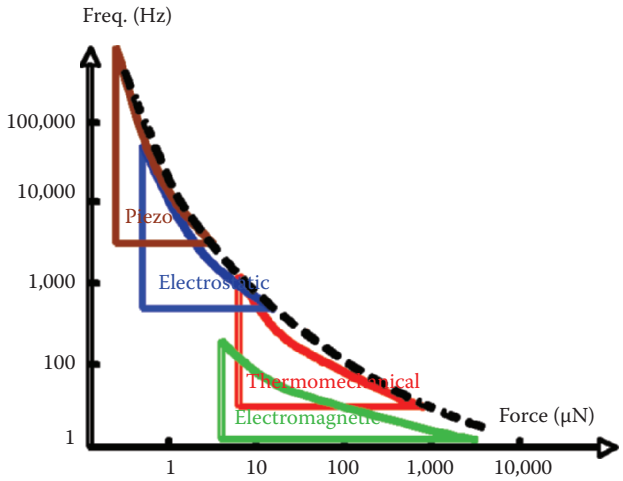
Besides different types of monolithic electrostatic micromotors,[19,25] electrostatic actuators have been used for hybrid mounted micromotors;[26] microvalves;[28] mechanical resonators for use in, for example, gyros and accelerometers;[27] displacement actuators for optical components (e.g., for positioning micromirrors);[28] and switches.[29] An electrostatic microswitch developed by this author is illustrated in Figure 8.13. Upon applying a bias between the cantilever and the substrate, two metal gold pads make physical contact enabling large currents to flow. A mechanical switch as shown has advantages over an electronic switch, as its off-impedance (air gap) is infinite and its on-impedance (metal contact) is very low.

Summary Electrostatic Actuators: Performance and Modeling

Electrostatic fields can exert great forces, but generally only across very short distances (1 µm). The extremely low current consumption associated with electrostatic devices makes for highly efficient actuation and the high speeds (up to 100 kHz) and ease of fabrication of electrostatic devices has enabled many applications (see above). In Figure 8.14, where

* A detailed description of an electrostatic eccentric drive micromotor (wobble motor) can be found in Price et al.[23]



1. Stroke: 1 μm
2. Maximum speed: 100 kHz
3. Intermediate force density
4. Easy to fabricate
5. Voltage: ~100 V
6. Footprint: 10 μm to 1 mm
7. Maximum electric field before breakdown (approximately 3×10^8 Vm^{-1})
8. Maximum electrostatic energy density, U_m' (in J/m^3): 4.0×10^5 Jm^{-3}

FIGURE 8.14 Summary of electrostatic actuators.

we plot frequency versus force, we summarize some of the most salient electrostatic actuator characteristics in comparison to actuators based on other principles.

In Figure 8.15 we generalize the description of the dynamics of an electromechanical system. We employ x as the direction of displacement (instead of z; see above) and K for a combined stiffness constant (instead of k; see above). The differential equation, describing the electrical equivalent circuit shown here (Figure 8.15b), is as follows:

$$L\frac{d}{dt}\left(\frac{dQ}{dt}\right)+R\left(\frac{dQ}{dt}\right)+\frac{1}{C}Q(t)=V_i$$

and with $$\frac{d}{dt}\left(\frac{dQ}{dt}\right)=\ddot{Q}(t) \quad \text{and} \quad \frac{dx}{dt}=\dot{Q}(t)$$

$$L\ddot{Q}(t)+R\dot{Q}(t)+\frac{1}{C}Q(t)=V_i \qquad (8.36)$$

where V_i is the input voltage and V_0 the output voltage. L is inductance, R is resistance, and C is capacitance. For the mechanical equivalent circuit (Figure 8.15a), the differential equation is as follows:

$$m\frac{d}{dt}\left(\frac{dx}{dt}\right)+b\left(\frac{dx}{dt}\right)+Kx(t)=F$$

with $$\frac{d}{dt}\left(\frac{dx}{dt}\right)=\ddot{x}(t) \quad \text{and} \quad \left(\frac{dx}{dt}\right)=\dot{x}(t)$$

$$m\ddot{x}(t)+b\dot{x}(t)+Kx(t)=F \qquad (8.37)$$

where the external force F is the input, the displacement x is the output, b is damping, m is the mass, and K is the stiffness.

The modeling equations gathered above are in the time domain, but often analysis of a system is easier

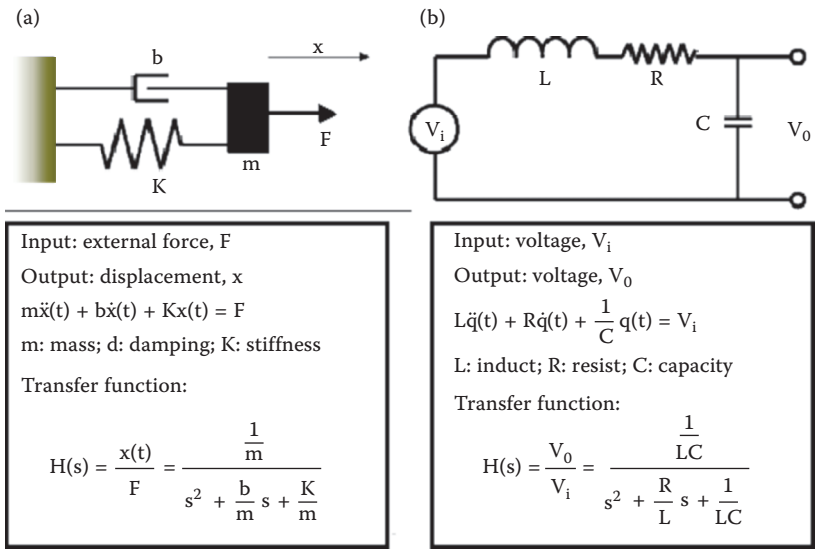


FIGURE 8.15 General description of the dynamics of an electromechanical system.

to perform in the frequency domain. In order to convert these equations to the frequency domain, we apply the Laplace transform to determine the transfer function [$H(s)$] of the system. As a consequence functions with a real dependent variable (such as time) are converted into functions with a complex dependent variable (such as frequency, often represented by s), which are easier to manipulate. The transfer function of the system then is the ratio of the output Laplace transform to the input Laplace transform assuming zero initial conditions. Many important characteristics of dynamic or control systems can be determined from the transfer function. The general procedure to find the transfer function of a linear differential equation from input to output is to take the Laplace transforms of both sides assuming zero conditions and to solve for the ratio of the output Laplace over the input Laplace. For the electrical case the transfer function is as follows:

$$H(s) = \frac{V_0}{V_i} = \frac{\frac{1}{LC}}{s^2 + \frac{R}{L}s + \frac{1}{LC}} \qquad (8.38)$$

And for the mechanical case, it is as follows:

$$H(s) = \frac{x(t)}{F} = \frac{\frac{1}{m}}{s^2 + \frac{b}{m}s + \frac{K}{m}} \qquad (8.39)$$

Piezoelectricity

Introduction

In 1880, Pierre Curie and his brother Paul-Jacques discovered that external forces applied to single crystals of quartz and some other minerals (e.g., Rochelle salt) generate a charge on the surface of these crystals. The charge, they found, is roughly proportional to the applied mechanical stress (force per unit area). This is called the *direct piezoelectric effect*. The effect received its name in 1881 from Wilhelm Hankel, and it remained a curiosity until 1921, when Walter Cady discovered that a quartz resonator could be used for stabilizing electronic oscillators.[30] Piezoelectric materials exhibit the inverse effects as well: an applied voltage generates

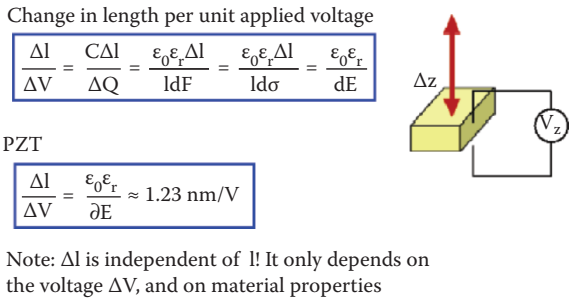

FIGURE 8.16 The inverse piezoelectric effect. Used to build actuators.

a deformation of the crystal (Figure 8.16). Lippman predicted this effect from thermodynamic principles, and the Curie brothers confirmed it experimentally a year later (1881). In the direct case, the crystals work like sensors; in the indirect case, piezoelectrics exhibit an actuation behavior. The mechanical waves generated by piezoelectrics are also called *acoustic waves*. Acoustic wave devices are so named because their detection mechanism is a mechanical, or acoustic, wave. Piezoelectric acoustic wave sensors apply an oscillating electric field to create a mechanical wave, which propagates through the substrate and is then converted back to an electric field for measurement. As the acoustic wave propagates through or on the surface of the piezoelectric material, any changes to the characteristics of the propagation path affect the velocity and/or amplitude of the wave. Changes in velocity can be monitored by measuring the frequency or phase characteristics of the sensor and can then be correlated to the corresponding physical quantity being measured. Virtually all acoustic wave devices and sensors use a piezoelectric material to generate the acoustic waves.

Piezoelectric actuators follow mammalian muscle as the most ubiquitous actuator principle in nature. For example, bones possess piezoelectric properties.[31] Other biological materials that have been found to be piezoelectric include tendon, dentin, ivory, intestine, silk, elastin, wood, and the nucleic acids.

Piezoelectricity is not to be confused with ferroelectricity, discovered in 1920 by J. Valasek. Ferroelectricity is the property of a spontaneous or induced electric dipole moment. In crystals of Rochelle salt ($NaKC_4H_4O_6 \cdot 4H_2O$), the unit cells

have a spontaneous asymmetric charge distribution, and the orientation of this polarization can be switched by applying a field strong enough to drag the unsymmetrically placed ions into equivalent positions in the opposite direction. All ferroelectric materials are piezoelectric, but the converse is not always true. Piezoelectricity relates to the crystalline ionic structure; ferroelectricity relates to electron spin. Above the so-called *Curie temperature*, spontaneous polarization of a ferroelectric is lost, because thermal vibrations randomize the dipole orientations. The transition from a nonferroelectric to a ferroelectric state is analogous to the magnetic ordering transition in a ferromagnet below its Curie temperature. Ferroic materials are multifunctional materials, materials having both sensing and actuation functions. A large number of applications of ferroelectric materials exploit an indirect consequence of ferroelectricity, such as dielectric, piezoelectric, pyroelectric, and electrooptic properties. The biggest use of ferroelectric materials is as dielectrics in capacitors, ferroelectrics for thin films for nonvolatile memories, piezoelectric materials for medical ultrasound and imagining and actuators, and electrooptical materials for data storage and displays. Ferroelectric materials exhibit strong electrostriction.

Electrostriction, covered below, is a secondary coupling in which the strain is proportional to square of the electric field. Electrostriction, a property of all dielectrics but pronounced only for ferroelectrics, is similar to the piezoelectric effect in that it involves an increase in length parallel to an applied electric field. In electrostrictive materials, in contrast to piezoelectric materials, the direction of this small change in geometry does not reverse if the direction of the electrical field is reversed.

Mechanism of Piezoelectricity

A simplified model of piezoelectricity entails the notion of anions (–) and cations (+) moving in opposite directions under the influence of an electric field or a mechanical force. The forces generated by this motion cause lattice deformation for noncentrosymmetric crystals because of the presence of both high- and low-stiffness ionic bonds. The effect for quartz is illustrated in Figure 8.17. If the cell shown here is deformed along the x- or y-axis, the O-ion is displaced, and positive or negative charges are formed. As a result, all piezoelectric materials are necessarily anisotropic; in cases of central symmetry, an applied force does not yield an electric polarization. By applying mechanical deformations to piezoelectric crystals, electric dipoles are generated, and a potential difference develops when changing those mechanical deformations. Silicon is not piezoelectric because it is cubic and covalent rather than

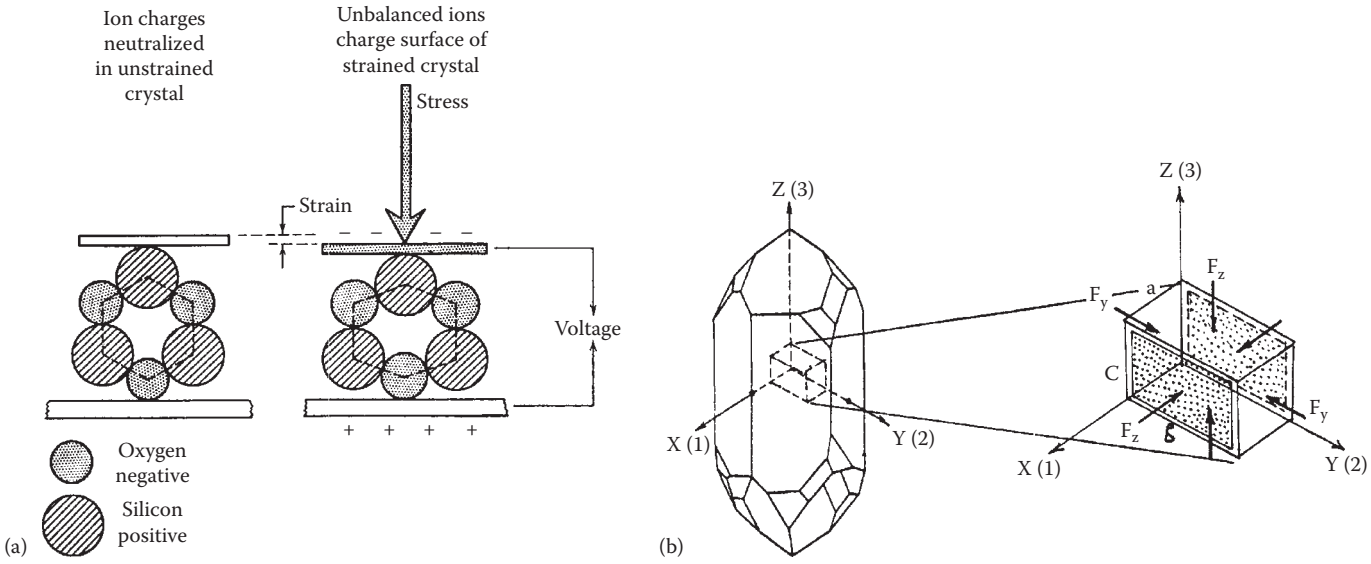

FIGURE 8.17 Piezoelectricity in an ionic crystal such as quartz. (a) Ion position in quartz lattice with and without applied stress. (b) Element cut from quartz crystal under stress.

ionic and noncentrosymmetric. It is important to remember that the potential and the associated currents in piezoelectric materials are a function of the continuously changing mechanical deformation. Therefore, typical and practical uses are in situations involving dynamic strains of an oscillatory nature.[32]

As we saw in Volume I, Chapter 2, the thousands of crystals found in nature can be grouped into 230 space groups on the basis of symmetry elements. Since the relative position of the symmetry elements in a crystal is not important, and only their orientation counts, the 230 space groups can be reduced to just thirty-two point groups. The thirty-two point groups further divide over the seven well-known crystal systems: triclinic, monoclinic, orthorhombic, tertragonal, trigonal, hexagonal, and cubic. Of the thirty-two point groups, twenty-one do not have a center of symmetry (i.e., they are noncentrosymmetric). The latter crystals possess one or more crystallographically unique directional axes, and all, except the 432 point group, show the piezoelectric effect along unique directional axes. Piezoelectric properties are thus present in twenty of the thirty-two different crystallographic point groups, although only a few of them are used. They are found also in amorphous ferroelectric materials. Of the twenty crystallographic classes, only ten display ferroelectric properties.

A more detailed understanding of piezoelectricity is based on an understanding of the piezoelectric equations describing the coupling between electric and mechanical strains in a piezoelectric material. Polarization and stress are vector and tensor properties, respectively, and in general, arbitrary components of each can be related via the piezoelectric effect. For this reason, piezoelectricity is a complicated property, and up to eighteen constants may be required to specify it. When a stress, σ (FA^{-1}), is applied to a slab of material cut from a piezoelectric material such as quartz, the resulting one-dimensional strain, ε, in the elastic range, can be written as (see Volume I, Chapter 4, "Stress-Strain Curve and Elasticity Constants"):

$$\varepsilon = S\sigma \tag{8.40}$$

which represents Hooke's law, where *S* stands for the compliance (S^{-1} = E = Young's modulus). With a potential difference applied across the faces of the piezoelectric, an electric field, *E* (Vm^{-1}), is established and we obtain the following (see Volume I, Equation 3.37):

$$D = \varepsilon_r E = \varepsilon_0 E(1 + \chi) = P \tag{8.41}$$

where D = electric displacement (or electric flux density)
ε_r = relative permittivity of the material (dimensionless)
E = electric field
ε_0 = permittivity of vacuum in $A \times s\ V^{-1} \times m^{-1}$
χ = electrical susceptibility
P = polarization, that is, the electric dipole moment per unit volume of material

Equation 8.40 contains only mechanical quantities, and Equation 8.41 contains only electrical parameters. Piezoelectric materials possess a special interlocking behavior in which electrical charges are produced by straining the material, and mechanical forces are produced by subjecting the material to an electric field.[33] For a one-dimensional piezoelectric material with electric field and stress in the same direction, according to the principle of energy conservation from thermodynamics, we can describe this situation as follows:[34]

$$D = d\sigma + \varepsilon(d)^{\sigma} E \tag{8.42}$$

$$D = e\varepsilon + \varepsilon(d)^{\varepsilon} E \tag{8.43}$$

where *d* represents a piezoelectric constant (charge density/applied stress) expressed in coulombs divided by newtons (C/N), and $\varepsilon(d)\sigma$ is the permittivity at constant stress [we added a "(*d*)" to distinguish the dielectric constant from the strain ε]. To work with *d* coefficients is useful when charge generators are contemplated, for example, in piezoelectric accelerometers. In the second expression, *e* stands for a piezoelectric constant (charge density/applied strain) in Cm^{-1}, and $\varepsilon(d)^{\varepsilon}$ is the dielectric constant at a constant strain. Solving for *E*, we can rewrite Equations 8.42 and 8.43 as follows:

$$E = -g\sigma + \frac{D}{\varepsilon(d)^{\sigma}} \tag{8.44}$$

$$E = -h\varepsilon + \frac{D}{\varepsilon(d)^{\varepsilon}} \tag{8.45}$$

where $g = d/\varepsilon\ (d)^{\sigma}$ is a piezoelectric constant (field/applied stress), also called a *voltage constant*, in V/m/N, and $h = e/\varepsilon\ (d)^{e}$ is a piezoelectric constant (field/applied strain) in V/m. The above set of equations describes the direct piezoelectric effect. The equations for the inverse effect are written as follows:

$$\varepsilon = dE + S^{E}\sigma \tag{8.46}$$

$$\varepsilon = gD + S^{D}\sigma \tag{8.47}$$

where d and g = piezoelectric constants given in mV^{-1} and mC^{-1}, respectively
S^{E} = compliance at constant field
S^{D} = the compliance at constant electric flux density

Solving Equations 8.46 and 8.47 for σ results in the following:

$$\sigma = -eE + E(Y)^{E}\varepsilon \tag{8.48}$$

$$\sigma = -hD + E(Y)^{D}\varepsilon \tag{8.49}$$

where $e = d/S^{E}$ and $h = g/S^{D}$ = piezoelectric constants given in N/V/m and N/C, respectively
$E(Y)^{E}$ = Young's modulus [we added a "(*Y*)" here to distinguish the Young's modulus from the electric field *E*] under constant electrical field
$E(Y)^{D}$ = Young's modulus under constant electric flux density

Equations 8.42 to 8.49 are known as the *piezoelectric constitutive relations*. They are summarized in Table 8.4, together with the definition of the four piezoelectric constants *d*, *e*, *g*, and *h*.

If no external field is imposed, according to Equations 8.41, 8.42, and 8.43, a stress, σ, will lead to the following polarization, *P*, or direct effect:

$$P = d\sigma \tag{8.50}$$

and, according to Equations 8.46 and 8.47, if there is no external stress applied, a field, *E*, will lead to the following strain and converse effect, ε:

$$\varepsilon = dE \tag{8.51}$$

so that the same constant—the piezoelectric coefficient *d*—is used for the direct and reverse effects.

The ratio of the converted energy of one kind (mechanical or electrical) stored at any instant in a piezoelectric to the input energy of the second kind (electrical or mechanical) is defined as the square of the coupling coefficient:

$$k = \sqrt{\frac{\text{mechanical energy stored}}{\text{electrical energy applied}}} = \sqrt{\frac{\text{electrical energy stored}}{\text{mechanical energy applied}}} \tag{8.52}$$

The electromechanical coupling coefficient, *k*, is thus a measure of the interchange of electrical and mechanical energy. It can be shown that *k* equals the geometric mean of the piezoelectric voltage coefficient (*g*) and the piezoelectric stress coefficient (*e*) and is indicative of the ability of a material to both detect and generate mechanical vibrations:[35]

$$k = \sqrt{ge} \tag{8.53}$$

To activate the maximum piezoelectric strain in a given crystal, the orientation dependence of the piezoelectric effect should be carefully considered.

Table 8.4 Piezoelectric Constitutive Equations and Definitions of Piezoelectric Parameters

Piezoelectric Equations	Equation Number in Text	Definitions of Constants	SI Units
$D = d\sigma + \varepsilon(d)\sigma E$	8.42	d = charge density/applied stress	C/N
$D = e\varepsilon + \varepsilon(d)\varepsilon E$	8.43	e = charge density/applied strain	C/m
$E = -g\sigma + D/\varepsilon(d)\sigma$	8.44	g = field/applied stress	V/m/N
$E = -h\varepsilon + D/\varepsilon(d)\varepsilon$	8.45	h = field/applied strain	V/m
$\varepsilon = dE + S^{E}\sigma$	8.46	d = strain/applied field	m/V
$\varepsilon = gD + S^{D}\sigma$	8.47	g = strain/applied charge density	m/C
$\sigma = -eE + E(Y)^{E}\varepsilon$	8.48	e = stress/applied field	N/V/m
$\sigma = -hD + E(Y)^{D}\varepsilon$	8.49	h = stress/applied charge density	N/C

For the general case of a piezoelectric crystal, rather than a one-dimensional piezoelectric as treated above, the piezoelectric constitutive relations must be generalized. The generalized elastic response of a piezoelectric crystal to an electric field (see Equation 8.51) may then be expressed as follows:

$$\varepsilon_k = \sum_{i=1}^{3} \mathbf{d}_{ik}\mathbf{E}_i \tag{8.54}$$

and the polarization in the absence of a field, from Equation 8.50, as follows:

$$\mathbf{P}_i = \sum_{k=1}^{6} \mathbf{d}_{ik}\sigma_k \tag{8.55}$$

In these equations, i = 1, 2, and 3 make up the indices of the components of polarization and k = 1, 2, …, 6 the indices of the components of mechanical stress and strain. In the piezoelectric constants, the first subscript refers to the direction of the field; the second subscript refers to the direction of the stress. The subscripts 1, 2, and 3 indicate the *x*-, *y*-, and *z*-axes, respectively. For example, in d_{33}, i = 3 indicates that the polarizing electrodes are perpendicular to the 3-axis (i.e., *z*-axis), and the piezoelectric-induced strain or applied stress is in the 3-direction (along the *z*-axis) as well. For the coupling coefficient, *k* (Equation 8.53), the same notation is used. The above expressions are equivalent to writing (strain tensor) = (d tensor) × (electric field vector) and (polarization vector) = (d tensor) × (stress tensor), respectively. Piezoelectricity, we saw in Volume I, Chapter 2, on crystallography, is an example of a vector-tensor effect; an electric field (vector) causes a mechanical deformation (tensor). Elastic deformation under the influence of a stress tensor is an example of a tensor-tensor effect.

On the basis of this notation, we can now generalize the constitutive relations as:

$$\mathbf{D}_i = \mathbf{d}_{ik}\sigma_\kappa + \varepsilon(\mathbf{d})_{ik}\sigma\mathbf{E}_i \tag{8.56}$$

and:

$$\varepsilon_k = \mathbf{d}_{ik}\mathbf{E}_i + \mathbf{S}^{E}_{ik}\sigma_k \tag{8.57}$$

where $\mathbf{D}_i$ = electric displacement vector (3 × 1), C/m²
$\mathbf{E}_i$ = electric field vector (3 × 1), V/m
σ_i = stress (force/unit area) tensor (6 × 1), N/m²
ε_k = strain (relative displacement) tensor (6 × 1)
$\mathbf{d}_{ik}$ = a matrix of piezoelectric constants (3 × 6), m/V
$\varepsilon(\mathbf{d})_{ik}$ = permittivity measured at constant stress (3 × 3), As/Vm
$\mathbf{S}^{E}_{ik}$ = elastic compliance matrix when subjected to a constant electric field (6 × 6), m²/N

The other equations in Table 8.4 may be generalized in the same fashion.

From Volume I, Equation 4.83, we recall that the strain tensor has six components: σ_x, σ_y, σ_z for compression or tension and τ_{xy}, τ_{xz}, and τ_{yz} for the shear components. The piezoelectric behavior of a crystal can be completely described if the set of data related to the piezoelectric constants (d_{ik}), elastic compliances (S_{ik}), and permittivities [$\varepsilon(d)^{\sigma}_{ik}$] is given. This set can be introduced with a 9 × 9 matrix in which columns are associated with mechanical stresses and field strengths and rows refer to strains and polarizations:[36]

	σ_x	σ_y	σ_z	τ_{xy}	τ_{xz}	τ_{yz}	E_x	E_y	E_z
ε_x	S_{11}	S_{12}	S_{13}	S_{14}	S_{15}	S_{16}	d_{11}	d_{21}	d_{31}
ε_y	S_{21}	S_{22}	S_{23}	S_{24}	S_{25}	S_{26}	d_{12}	d_{22}	d_{32}
ε_z	S_{31}	S_{32}	S_{33}	S_{34}	S_{35}	S_{36}	d_{13}	d_{23}	d_{33}
γ_{xy}	S_{41}	S_{42}	S_{43}	S_{44}	S_{45}	S_{46}	d_{14}	d_{24}	d_{34}
γ_{xz}	S_{51}	S_{52}	S_{53}	S_{54}	S_{55}	S_{56}	d_{15}	d_{25}	d_{35}
γ_{yz}	S_{61}	S_{62}	S_{63}	S_{64}	S_{65}	S_{66}	d_{16}	d_{26}	d_{36}
P_x	d_{11}	d_{12}	d_{13}	d_{14}	d_{15}	d_{16}	ε_{11}	ε_{12}	ε_{13}
P_y	d_{21}	d_{22}	d_{23}	d_{24}	d_{25}	d_{26}	ε_{21}	ε_{22}	ε_{23}
P_z	d_{31}	d_{32}	d_{33}	d_{34}	d_{35}	d_{36}	ε_{31}	ε_{32}	ε_{33}

(8.58)

This matrix is symmetrical ($S_{ik} = S_{ki}$, $d_{ik} = d_{ki}$, and $\varepsilon_{ik} = \varepsilon_{ki}$) and reduces to forty-five different terms, including twenty-one compliances, six permittivities, and eighteen piezoelectric constants. In the top left of this matrix (rectangular box), we recognize Equation 4.83, but because of the presence of piezoelectricity, the matrix is this much larger. For simplicity, we have replaced $\varepsilon(d)^{\sigma}_{ik}$ by ε_{ik} in the above matrix. A further simplified notation with one subscript is often introduced for dielectric constants: $\varepsilon_{11} = \varepsilon_1$, $\varepsilon_{22} = \varepsilon_2$, and $\varepsilon_{33} = \varepsilon_3$. For the defined orientation of the crystallographic axes, $\varepsilon_{ik} = 0$ for $i \neq k$.

For crystalline quartz, the eighteen remaining piezoelectric constants further reduce to two:

$$d_{ik} = \begin{bmatrix} d_{11} & d_{12} & 0 & d_{14} & 0 & 0 \\ 0 & 0 & 0 & 0 & d_{25} & d_{26} \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (8.59)$$

with $d_{11} = -d_{12} = -d_{26}/2 = 2.31$ pC/N and $d_{14} = -d_{25} = 0.73$ pC/N. The meaning of d_{14} is as follows: a torsion stress of 1 N/m^2 around the axis 1 (x) of quartz (direction 4, or xz) induces a charge density of 0.73 pC/N in two metal plates on the material in direction 1 (x).

Exercise 8.1:

A piezoelectric ceramic of 1 cm thickness in the 3-direction and 10 cm length in the 1-direction is subjected to a potential of 0.01 volts in the 3-direction, and the resulting change in length is 10^{-11} cm. What is the numerical value and subscript of the d constant? Answer: d_{31} = strain developed/field applied = (10^{-11} cm/10 cm)/(0.01 V/0.01 m) = 10^{-12} mV^{-1}.

Exercise 8.2:

If a voltage V is applied across the thickness of a piezoelectric slab, the displacements ΔL, ΔW, and Δt along the length, width, and thickness directions, respectively, are given by $\Delta L = d_{31} \times V \times L/t$, $\Delta W = d_{31} \times V \times W/t$, and $\Delta t = d_{33} \times V$, where L and W are the length and width of the plate, respectively, and t is the thickness or separation between the electrodes. When a force F is applied along the length, width, or thickness direction of the same slab, a voltage V is measured, given in each of the three cases as $V = d_{31} \times F/\varepsilon \times L$, $V = d_{31} \times F/\varepsilon \times W$, and $V = d_{33} \times F \times t/\varepsilon \times L \times W$.

At frequencies far below the resonance, piezoelectric transducers are fundamentally capacitors. Since, in a capacitor, the voltage V is related to the charge Q via the capacitance C ($Q = CV$), the charge coefficients d_{ik} are related in the same way to the voltage coefficients g_{ik} via ε_{ik}, or:

$$d_{ik} = \varepsilon (d)^{\sigma}_{ik} . g_{ik} . \varepsilon_0 \quad (8.60)$$

with ε_0 being the permittivity of free space. At resonance, the dielectric constant is reduced by a factor of (1 – k), where k is the coupling coefficient of the mode in question.

Overview of Types of Acoustic Waves

Introduction

Acoustic wave devices involve piezoelectric substrates or the coupling of piezoelectric materials to nonpiezoelectric structures to (e.g., a Si cantilever equipped with a thin film of piezoelectric ZnO). These devices are described by the mode of sound wave propagation through the piezoelectric substrate or through the linked nonpiezoelectric material. Primarily, their velocities and displacement directions distinguish sound wave types. It is important to remember here that acoustic waves are the result of induced particle vibration that depends on the elastic properties of the solid. In Table 8.5 we summarize several, but not all, of the wave modes possible in solids.

Metal transducers launch acoustic waves at ultrasonic frequencies and the type and resonant frequency of such waves are fixed by the piezoelectric crystal orientation, the thickness (t) of the piezoelectric used, and the geometry of the metal transducers. The resulting mechanical waves are called *transverse* or *shear waves* when the particle displacement is perpendicular to the direction of the wave propagation. Shear waves cannot propagate in fluids, and in a solid they typically travel at half the velocity of a longitudinal wave in the same material. In contrast, compressional or longitudinal acoustic waves are defined when particle displacement is parallel to

Table 8.5 Acoustic Wave Types in Solids

Wave Type	Particle Vibrations
Longitudinal	Parallel to wave direction
Transverse (shear)	Perpendicular to wave direction
Surface (Rayleigh)	Elliptical orbit, symmetrical mode
Plate (Lamb)	Component perpendicular to surface (extensional wave)
Plate (Love)	Parallel to plane layer, perpendicular to wave direction

the direction of the acoustic wave travel, and these waves can be transmitted in solids and liquids.

Bulk Acoustic Wave Devices

While bulk acoustic waves (BAWs) propagate through the volume of the piezoelectric substrate, the propagation of surface acoustic waves (SAWs) or Rayleigh waves is restricted to a distance of about one acoustic wavelength from the piezoelectric substrate surface. Rayleigh waves are somewhat similar to water waves in that the motion of particles is both longitudinal and transverse in a plane containing the direction of propagation and the normal to the surface.

A commonly used BAW device is the thickness shear mode (TSM) resonator shown in Figure 8.18. In TSM mode, bulk transverse waves with particle displacement parallel to the surface of the sensor are generated. Such waves, on propagation into a liquid, suffer severe attenuation of the acoustic energy due to the viscous forces in the liquid. The device pictured in Figure 8.18 is more commonly known as a *quartz crystal microbalance* (QCM) and is used, among other things, to measure deposited metal thickness in an evaporation station (see Volume II, Figure 7.2a). It consists of an AT-cut quartz disc with metal electrodes on opposite sides to effect the application of an oscillating electric field. A quartz AT cut is made normal to the *y*-axis but rotated 35.25° from the *z*-axis. In this direction, quartz has a zero temperature coefficient at 40°C, making the AT cut ideal for frequency control applications. Quartz is a hexagonal crystal (see Figure 8.17), and if the electrical field is aligned with the *y*-axis, the resulting deformation is a shear along the neutral *z*-axis. To achieve a shear motion, the cut must be normal to the *y*-axis so that charging electrodes placed on the two faces of the wafer can produce the field. The thickness (*t*) of the quartz

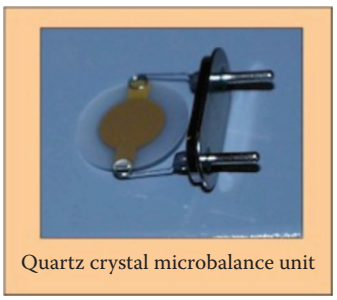

FIGURE 8.18 Quartz crystal microbalance.

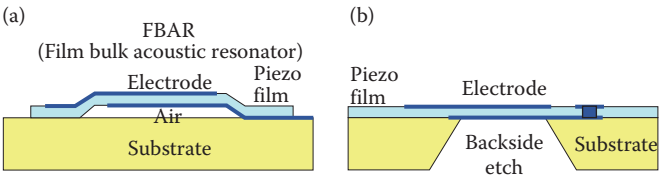

FIGURE 8.19 Two methods to make film bulk acoustic resonators (FBARS). The piezo film is typically aluminum nitride (AlN).

plate determines the wavelengths (λ) of the fundamental (n = 1) and harmonic resonances through the expression $\lambda = 2t/n$ (n = 3, 5, 7). Consequently, the resonant frequency for the fundamental mode is restricted by the thickness *t* of the quartz wafers to the range of approximately 5–20 MHz.

A more recent type of BAW device is a film bulk acoustic resonator (FBAR) that is used in mobile telephones. FBARs feature a $Q > 400$ at 1.9 GHz and often use aluminum nitride (AlN) as the piezoelectric material. The major difference between an FBAR and the QCM of Figure 8.19 is that the AlN thin film piezoelectric is much thinner than the quartz cut. Two types of FBAR constructs are shown in Figure 8.19. Figure 8.19a involves the etching of a sacrificial support layer below the piezofilm film. Figure 8.19b consists of etching the substrate from the back of the wafer to the front surface creating a so-called *pothole structure*.

Surface Acoustic Waves

It was Lord Rayleigh, in 1887, who discovered the surface acoustic wave (SAW) mode of sound propagation and predicted their properties. Named for their discoverer, Rayleigh waves have a longitudinal and a vertical shear component that couple with a medium in contact with the device's surface. Rayleigh waves are also of interest to geologists since these surface waves are excited by earthquakes.

A SAW device, as illustrated in Figure 8.20, comprises a thick ST-cut quartz plate and two interdigital metal transducers (IDTs).* In a typical "delay line" configuration, input and output IDTs generate or receive Rayleigh waves on the same side of a piezoelectric substrate. It was White and Voltmer[40]

* An interdigital transducer (IDT), or interdigitated transducer, is a device which consists of two interlocking comb-shaped metallic coatings.

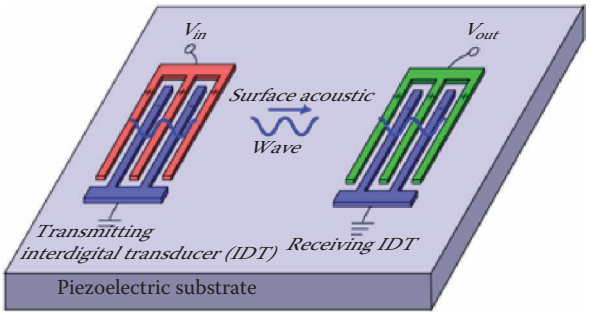

FIGURE 8.20 Surface-acoustic wave device; see also the hygrometer in Figure 8.26.

who pioneered the marriage of piezoelectricity with microelectronics through the demonstration that photolithographic techniques could be employed to deposit IDTs on piezoelectric substrates to excite Rayleigh waves. Rayleigh waves have a velocity that is ~5 orders of magnitude less than the corresponding electromagnetic wave, making Rayleigh surface waves among the slowest to propagate in solids. The wave amplitudes are typically ~10 Å, and the wavelengths range from 1 to 100 μm. The frequency of a SAW device is determined by the "finger" spacing of the IDTs ranging from 30 to 500 MHz (so they can be more than ten times faster than a QCM).

The surface particles in a Rayleigh wave move elliptically, resulting in a wave consisting of both shear and compressional components. The latter provokes an important attenuation effect in liquids that prevents the application of SAW devices in such media. An exception to this loss of sound energy occurs for devices using waves that propagate at a velocity lower than the sound velocity in the liquid. Regardless of the displacement components, such modes do not radiate coherently and are thus relatively undamped by liquids [see next section, on flexural plate wave (FPW) devices].

Flexural Plate Waves

A final important category of surface-launched acoustic wave sensors is those composed of very thin plate devices, where the thickness of a piezoelectric substrate is reduced to a dimension on the order of the acoustic wavelength itself. These devices use a thin piezoelectric substrate, or plate, as an acoustic waveguide that confines the acoustic energy between the upper and lower surfaces of the plate. The devices that generate such waves are termed *FPW devices*, as illustrated in Figure 8.21, and the waves they generate are called *Lamb waves*. Although surface-excited, the generated Lamb waves travel through the bulk of the piezoelectric membrane, and since both surfaces undergo displacement, detection may occur on either side. This is a very important advantage, as one side may feature the IDTs that must be isolated from, say, conducting liquids or corrosive gases, while the other side can be used as a sensing surface. Lamb waves generated in a plate of finite thickness can be of both symmetric and antisymmetric modes when referring to the median plane of the plate. Since the piezoelectric plate is so thin, the operating frequencies of FPW devices are substantially lower than for other surface-launched acoustic wave devices (2–7 MHz). As a consequence of the minimal thickness of the plate, the wave velocity is lower than the compressional velocity of sound in liquids. Accordingly, compressional waves are not coupled in liquids, resulting in less attenuation of acoustic energy. This is a consequence of Snell's law: the acoustic wave is trapped in the plate much as a light wave is trapped in an optical waveguide. This means that FPWs can even be used in liquids.

A practical FPW device, as shown in Figure 8.21, has a design similar to that of a SAW device. The basic elements of an FPW device consist of a composite plate of low-stress thin substrate material (e.g., 0.8–4-μm silicon nitride), a thin zinc oxide film (0.3–1.5 μm) as piezoelectric, and a pair of aluminum IDTs on the ZnO layer. IDTs are positioned in a way to form a delay-line configuration. A metal ground plane (0.2–05 μm thick) is sandwiched between the silicon nitride and piezoelectric layer. A chemical sensitive film may be deposited on the opposite side of the membrane. The IDTs launch and receive the plate waves (e.g., the 0th-order antisymmetric Lamb waves*) and, together with an amplifier, form a feed-

* Lamb waves are associated with Rayleigh waves on a plate whose thickness is smaller than the acoustic wavelength. They can be considered as two Rayleigh waves propagating on both sides of the thin plate. Two kinds of waves can propagate through the plate independently, namely the symmetric and the antisymmetric waves. The A_0 wave is the antisymmetric Lamb wave with the lowest phase velocity. This makes the wave suitable for liquid sensing because the A_0 wave does not excite compressional waves in a loading liquid and thus reduces scattering energy if its phase velocity is lower than the sound velocity of liquid. The A_0 mode Lamb wave sensor is also called the *FPW sensor.*

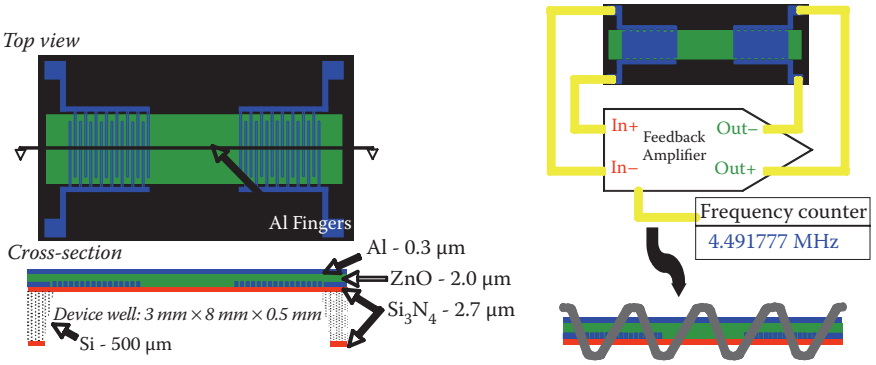

FIGURE 8.21 Construction and operation of a flexural pate wave device. (Courtesy of Dr. Dick White, University of California, Berkeley.)

back oscillator whose output frequency may provide a measure of the mass per unit area of the membrane, including a chemically sensitive film deposited on it. Summarizing the differences between an FPW device and a SAW device: 1) FPW devices operate at lower frequencies (a few megahertz as opposed to hundreds of megahertz for SAW sensors); 2) the IDTs are deposited on the opposite side of the FPW sensing material, and thus the sensor can be easier applied to liquids because the IDT electrodes are insulated from the liquid; and 3) the plate thickness is much smaller than the acoustic wavelength. FPW devices offer high mass sensitivity at much lower operating frequency than SAW devices.

Piezoelectric actuators generally produce very strong forces and very small motions that can be amplified, for example, by making the piezoelectric material part of a bimorph or a stack (Figure 8.22). Stacked structures attain larger displacements but are more difficult to implement in a miniaturized device. Piezo materials operate at high speed and return to a neutral position when the power is switched off. Alternating currents produce oscillations in a piezoelectric, and operation at the specimen's fundamental resonant frequency produces the largest elongation and at the highest power efficiency.

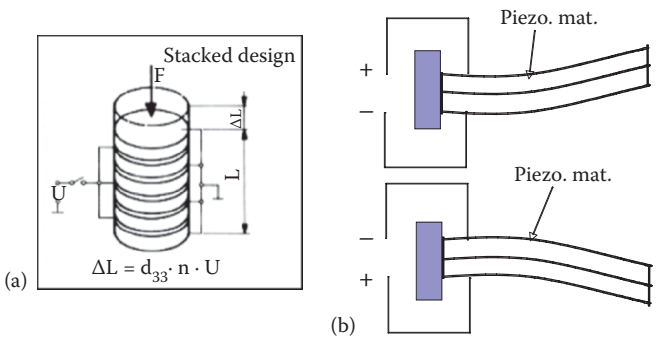

FIGURE 8.22 Piezoelectric stack actuator (a) and piezoelectric bimorph actuator (b).

Overview of Piezoelectric Materials

The first extensively used piezoelectric materials were naturally occurring crystals —quartz and Rochelle salt ($NaKC_4H_4O_6 \cdot 4H_2O$). Quartz has great physical and chemical stability but only a small coupling coefficient, k. Applications of quartz includes oscillators and resonators (see, for example, the quartz angular rate sensor based on a tuning fork in Figure 5.1). Rochelle salt has a great piezoelectric effect, but it is soluble in water and has poor temperature characteristics. It has been used in various transducers such as phonograph pickups.

In synthetic piezoelectrics, ceramics formed by many tightly compacted crystallites are most popular. Many piezoelectric materials, such as barium titanate ($BaTiO_3$), lead titanate ($PbTiO_3$), lead zirconate titanate (PZT), lead lanthanum zirconate titanate (PLZT), lead magnesium niobate (PMN), potassium niobate ($KNbO_3$), potassium sodium niobate ($K_xNa_{1-x}NbO_3$), and potassium tantalate niobate [$K(Ta_xNb_{1-x})O_3$], have a perovskite structure, that is, a structure of the type ABO_3. These ceramics are all ferroelectrics. As we saw in Volume I, Chapter 2, this absence of a center of symmetry in the crystal structure gives rise to spontaneous polarization. The crystal structure is cubic above the Curie temperature and tetragonal as it cools down. To align the

dipoles in the compacted monocrystals in the same direction (i.e., to polarize or pole them), they are subjected to a strong electric field during their fabrication process. Above the Curie point, the dipole directions in ferroelectric materials have random orientations. To align the dipoles, fields of 10 $kVcm^{-1}$ are common at temperatures slightly above the Curie temperature. The ceramic is then cooled while maintaining the field. When the field is removed, the crystallites cannot reorder in random form because of the mechanical stresses accumulated, resulting in a permanent electric polarization.

Barium titanate was the first material to be developed as a piezoceramic (see also Volume I, Figure 2.10, where the use of this material as a pyroelectric was highlighted). It was discovered independently, in the United States (Waigner and Salomon, 1942), the Soviet Union (Wul and Goldman, 1945), and Japan (Miyake and Ueda, 1946). Applications include detection of mechanical vibration, construction of actuators, and generation of acoustic and ultrasonic vibrations.

PZT is a solid solution of $PbTiO_3$ (tetragonal, with six poling directions) and $PbZrO_3$ (rhombohedral, with eight poling directions). This piezoceramic comes in various compositions such as PZT-4, PZT-5, PZT-5A, and PZT-5H. It was discovered in 1955 by Takagi, Shirane, and Sawagachi in Japan and Jaffe in the United States. The material has a high Curie temperature and is used in devices such as ceramic filters and piezoelectric igniters. Important for MEMS, PZT can be fashioned in thin film form by RF sputtering and rapid thermal annealing and subsequent poling. Alternatively, a sol-gel process is used to fabricate these films. One obtains a piezoelectric material with a relative dielectric constant of more than 1000 this way.[41] Abe and Reed[42] prefer sputtering and argue that the sol-gel technique is less attractive for MEMS applications, given that a 1-µm-thick film would require repeated spin coatings and pyrolysis steps. They prepared PZT films by sputtering from a composite target and found substrate heating during deposition to be crucial to transform the films into the perovskite phase during subsequent annealing. Piezoelectric thin films, such as PZT, zinc oxide (ZnO), and aluminum nitride (AlN), have the cost advantage over crystalline materials. Among these three, the electromechanical coupling effect of PZT is 3 to 9 times larger and the dielectric constant 100 times larger than that of AlN and ZnO, which makes PZT potentially the best candidate for thin film acoustic sensors. However, the polycrystalline structure of PZT and the required heat treatment during the coating process complicate the realization. A problem with all these polycrystalline materials in general relates to their temperature sensitivity and aging (loss of piezo properties) when approaching the Curie temperature.

Polymers such as polyvinylidene fluoride (PVDF), lacking central symmetry, also display piezoelectric properties. This piezopolymer is also pyroelectric, capable of converting changes in temperature to electrical output (see below). Compared with quartz and ceramics, piezofilm is obviously more pliant and lighter in weight. In addition, it is rugged, quite inert, and low cost. This engineering material could provide a sensing solution for vibration sensors, acceleration and shock sensors, passive infrared (IR) sensors, solid state switches, and acoustic and ultrasonic sensors. It should be noted that the peak reversible stress and strain developed by PVDF approximate 3 MPa and 0.1%, respectively. The latter values are rather small, and as for piezoelectric ceramics and magnetostrictive materials (see below), mechanical amplifiers are required to produce the larger displacements needed for many applications. A 200-fold mechanical amplification is required to make PVDF's peak strain similar to that of mammalian muscle.[43] Table 8.6[44,45] summarizes some of the physical properties making PVDF an interesting sensor material.

AlN is a wide-bandgap semiconductor and an excellent candidate for the integration of acoustic wave devices on chips with silicon-based electronics. AlN is a stiff and light material that exhibits excellent piezoelectric properties, including an electromechanical coupling coefficient of 0.088 and a high in-plane acoustic velocity of ~5700 m/s. As a piezoelectric ceramic, aluminum nitride is compatible with standard silicon MEMS processing and has found widespread use in FBARs (see Figure 8.19) and SAW devices (Figure 8.20) AlN may also prove to be useful for the integration of mechanical devices and in the field of packaging of bio-MEMS

Table 8.6 Typical Properties of Piezofilm (Uniaxially Oriented Film)

devices because of its superior thermal conductivity 130–140 (W/mK, room temperature to 100°C) and nontoxicity. The material is often grown by DC magnetron sputtering or by LPCVD on a (001) sapphire substrate (heated to 300–400°C) and can also be epitaxially grown on <111> silicon. Even atomic layer deposition (ALD) has been used to deposit AlN.

The last piezoelectric material we cover here is ZnO, a very versatile piezoelectric that has been used in cantilever-beam accelerometers, gas sensors, FPW devices, IR detectors, anemometers, tactile sensor arrays, etc. A typical change in length per electric field unit (perpendicular to the field E) for ZnO equals 5×10^{-10} C/N compared with 100–200×10^{-10} C/N for PZT-type thin film ceramics. Techniques that have been used for zinc-oxide thin film deposition include RF and dc sputtering, chemical vapor deposition, ion plating, reactive magnetron sputtering, and planar magnetron sputtering (in Polla and Muller[46] and references therein). For thin film deposition of ZnO, planar magnetron sputtering appears to give the best piezoelectric and pyroelectric characteristics; using this technique highly oriented ZnO films have been deposited on SiO_2, polycrystalline silicon, and bare silicon substrates. The compatibility of ZnO with silicon processing is demonstrated, for example, in the commercially available acoustic sensor from Honeywell Corporation, shown in Figure 8.27. The microphone chip illustrated here incorporates ZnO deposited on a silicon substrate, including signal-conditioning circuitry. Muller[47] found the best thin film crystallinity at a sputtering power of 200 W with a 10 mTorr[46] ambient gas mixture consisting of an equal mix of oxygen and argon. The distance between the substrate and target measures about 4 cm, with the substrate temperature maintained at 230°C during deposition. Tjhen et al.[48] characterized the thin film properties of sputtered ZnO and found the electrical properties to be sensitive to substrate material, stress, and surface condition.

The considerations in designing sensors with AlN, ZnO, or PZT films include the following:

1. Value of electromechanical coupling
2. Good adhesion to the substrate
3. Resistance to environmental effects (e.g., humidity, temperature)
4. VLSI process compatibility
5. Cost effectiveness

To further improve the mechanical properties of piezoelectric sensors, piezoelectric composite materials are sometimes used. These are heterogeneous systems consisting of two or more different phases, of which at least one shows piezoelectric properties. Hirata et al.,[49] for example, used LIGA to make arrays of PZT rods with diameters below 20 μm and an aspect ratio of over 5. The PZT rods are embedded in a polymer matrix to make a PZT/polymer composite. The PZT slurry, average particle size 0.4 μm, is injected into a LIGA resist mold (for information on slurry casting of piezoceramics see Preu et al.[50] and Lubitz[51]). After solidification, the resist is removed by plasma etching, and the array of

ceramic posts is cast in an epoxy resin. Resolution of acoustic-imaging transducers, for example, for medical applications, should gain resolution as the PZT rods undergo further miniaturization as a result of minimized cross-talk in the array.

Typical piezoelectric materials are compared in Table 8.7. For a survey of inorganic ferroelectrics, refer to *Ferroelectric Transducers and Sensors*.[35] For a detailed review of ferroelectric polymers, refer to *Ferroelectric Polymers: Chemistry, Physics, and Applications*.[45]

Piezoelectric Applications

Overview

When the characteristics of an acoustic path change, a change in acoustic output results. As the acoustic wave propagates through or on the surface of a piezoelectric material, changes to the characteristics of the propagation path affect the velocity and/or amplitude of the wave. Those changes in velocity can be monitored by measuring the frequency or the phase characteristics of the piezoelectric device and can then be correlated to the corresponding physical quantity being measured. In principle, then, all acoustic wave devices are sensors in that they are sensitive to many different physical parameters. The range of phenomena that can be detected by acoustic devices can be further expanded dramatically by coating the piezoelectric material or a structure coupled to it with materials that undergo changes in their mass, elasticity, or conductivity upon exposure to some physical or chemical stimulus. These sensors then may become pressure, torque, shock, and force detectors if under an applied stress the dynamics of the propagating medium change. They become mass, or gravimetric, sensors when particles are allowed to contact the propagation medium, changing the stress on it. They are turned into vapor sensors when a coating is applied that absorbs only specific chemical vapors. These devices work by measuring the mass of the absorbed vapor. A heating element under the chemical film can also be used to desorb chemicals from the device. If the coating absorbs specific biological chemicals in liquids, the detectors become biosensors.

Bulk ceramic piezoelectric devices, say on the basis of PZTs, have been widely used for decades, but thin film applications are more recent arrivals. Telecommunications constitutes the largest market today, accounting for about 3 billion acoustic wave filters annually, primarily for mobile cell phones. This use involves SAW devices, and lately, FBARs. These components are used as bandpass filters. Some of the new emerging applications for acoustic wave devices include all types of sensors for automotive applications (accelerometers and torque and tire pressure sensors), medical applications (chemical

sensors), and industrial and commercial applications (vapor, humidity, temperature, and mass sensors). Some of these sensors are capable of being passively and wirelessly interrogated (no sensor power source required). The use of piezoelectrics in actuators is also a growth area and includes micromotors, ignitors, bimorphs, impact printer heads, speakers, microphones, precision positioning stages, microscale surgical tools,[52] pumps, inchworm stepping motors, and tip-positioning stages for scanning tunneling microscope systems.

The small strains, usually less than 0.1%, and high stresses (e.g., 35 MPa) generated by piezoelectric devices have spawned a diverse range of actuator applications, as noted above (see also Figure 8.23 below; see Figure 1.11 for a micropiezopump from Animas-Debiotech's). Bulk piezoelectric transducers have also been used for a long time in medical ultrasound, in both passive and active modes.[53] In the passive mode, the transducer acts as a sound receiver only; it converts mechanical sound energy into an electrical signal. In the active mode (the converse effect), the transducer is an active sound transmitter; electrical energy is transformed into mechanical sound energy. Mostly, piezoelectrics are used in a pulse echo mode in which the transducers are used to simultaneously perform active and passive functions. A sound wave is propagated into the surrounding medium, and a faint echo is received after a small time gap due to the acoustic mismatch between the interface materials. This principle is used for ultrasonic imaging applications. When used in the human body with a sound velocity of 1500 ms^{-1}, the resolution varies from 1 mm to 50 μm for the frequency range of 1.5–3 MHz. The maximum frequency is dictated by the attenuation in the body, that is, 0.5 dB/cm MHz.

In the following we detail four of the applications mentioned above, namely, micromotors, pumps, acoustic-based chemical sensors, and acoustic imaging.

Piezoelectric Motors

Piezoelectric actuators, as Flynn et al.[41] point out, offer significant advantages over both electrostatic (see above) and electromagnetic (see below) actuators. With motors, for example, the greater the energy density that can be stored in the gap between rotor and stator, the greater the potential for converting

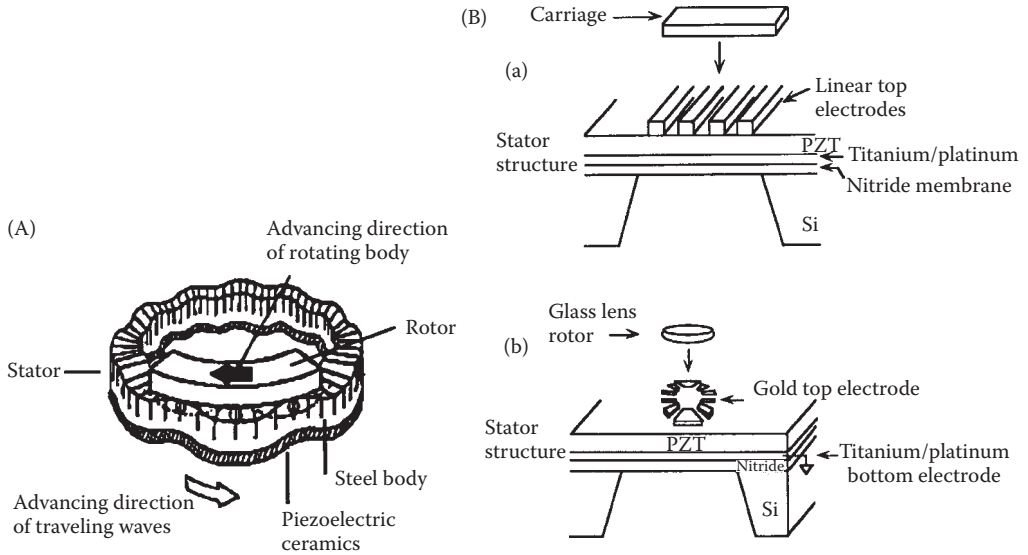

FIGURE 8.23 Piezoelectric motors. (A) Schematic of commercially available Panasonic ultrasonic motor: an electrically induced wave of mechanical deformation travels through a piezoelectric medium in the stator, moving the rotor body along through friction. (B) Thin-film lead zirconate titanate (PZT) motors. (a) Linear motor: the PZT stator is patterned onto a silicon membrane. The stator can deflect more because the nitride membrane is thin; titanium and platinum form the ground electrode, and the linear gold stripes are the top electrodes. A carriage is deposited on the stator by hand. (b) Rotary motor: identical to the linear motor except that the top electrodes are patterned in a circle. (After Flynn, A.M., L.S. Tavrow, S.F. Bart, R.A. Brooks, D.J. Ehrlich, K.R. Udayakumar, and L.E. Cross. 1992. Piezoelectric micromotors. *J Microelectromech Syst* 1:44.[41])

that energy to torque or useful work. In what follows, we compare the energy density one can store in the rotor/stator gap for various motor mechanisms. For electrostatic motors, the maximum energy density storable in the air gap, is determined by E_b, the maximum electric field before breakdown (approximately 3×10^8 Vm^{-1} for 1-μm gaps). From Chapter 7 we recall:

$$U'_m = \frac{\varepsilon_r \varepsilon_0 E_b^2}{2} \tag{7.36}$$

where $\varepsilon_r = \varepsilon_{air}$ represents the permittivity of air (almost equal to that of free space). This results in an energy density of 4.0×10^5 Jm^{-3}. With a piezoelectric motor made from ferroelectric material such as PZT, the energy density again is determined by the maximum electric field before breakdown. Thin film PZT can withstand high electric fields, about the same as an air gap ($E_b = 3 \times 10^8$ Vm^{-1}), but the dielectric constant is 3 orders of magnitude larger ($\varepsilon_{PZT} = 1300\ \varepsilon_{air}$) than air:

$$U'_m = \frac{\varepsilon_{pzt} \varepsilon_0 E_b^2}{2} \tag{8.61}$$

In principle then, the energy density also should be 3 orders of magnitude larger. In case of magnetic motors, the magnetic energy density, U'_m, stored in an air gap is given by:

$$U'_m = B^2/2\mu_0 \tag{8.62}$$

where B is the magnitude of the magnetic flux density in the gap and μ_0 the magnetic permeability of free space (see further below Equation 8.80). With magnetic actuators, the gap energy density, by pushing B into saturation (about 1.5 T), leads to 950,000 Jm^{-3}. The energy density stored in the rotor/stator gap for magnetic, electrostatic, piezoelectric, and SMA actuation (see below) are compared in Table 8.8.

Obviously, piezoelectric ultrasonic motors have an energy advantage. Other advantages, summarized from Flynn et al.,[41] include the following:

- Low voltages: no air gap is needed; mechanical forces are generated by applying a voltage directly across the piezoelectric film. With a 0.3-μm thin film, only a few volts are required, as opposed to hundreds of volts needed in air gap electrostatic motors.
- Geardown: motors can be fabricated without the need of a gearbox. Electrostatic wobble motors are also able to produce an inherent gear reduction but do not have the high dielectric advantage.
- No levitation: with electrostatic motors, levitation and flatness are very important in obtaining good sliding motion of the rotor around the bearing. The piezoelectric motor depends on friction so that no levitation is required, and it can be freely sized.
- Axial coupling: electrostatic motors require axial symmetry around the bearing. Since height is difficult to obtain with most nontraditional micromachining techniques (except for LIGA and pseudo-LIGA methods), a limited area is available for energy transduction. With the piezoelectric traveling-wave motors, linear or rotary motors can be built. As the stator is flat, with the rotor sitting on top of it, planar technologies are very capable of creating extra area to couple power out.
- Rotor material: the rotor can be of any material. A very important factor is that the conductivity of fluids being pumped with such motors does not affect the device, whereas an

Table 8.8 Comparing Energy Densities for Magnetic, Shape Memory Alloy, Electrostatic, and Piezoelectric Actuation

Principle	Maximum Work Energy Density	Equation	Special Drive Condition
Magnetic	9.5×10^5 Jm^{-3}	½ B^2/μ_0	1.5 T
Shape memory alloy	10.4×10^6 Jm^{-3} (from stress-strain isotherms)		1.4 W mm^{-3}
Electrostatic	4×10^5 Jm^{-3}	½ $\varepsilon_0 \varepsilon_{air} Eb^2$	3×10^8 Vm^{-1},1-μm gap in air
Piezoelectric	5.2×10^7 Jm^{-3}	½ $\varepsilon_0 \varepsilon_{PZT} Eb^2$	3×10^8 Vm^{-1},1-μm-thick lead zirconate titanate film

electrostatic motor would be shunted by a conductive liquid.

- Holding torque: because they are based on friction, piezoelectric ultrasonic motors can maintain holding torque even in the absence of applied power.

A schematic of a commercially available piezoelectric motor from Panasonic, which uses an ultrasonic traveling wave, is shown in Figure 8.23A. Two bulk ceramic PZT layers, each segmented with alternating poled regions, are placed on top of one another. For a given polarity of the applied bias, one segment contracts and the neighboring segment expands. With the two ceramic pieces put on top of each other with their segmented areas out of phase, any point on the stator then moves with the rotor being pulled along the stator surface through frictional coupling.

Thin film PZT linear and rotary motors by Flynn et al.[41] and Udayakumar et al.[54] are illustrated in Figure 8.23B. The stators in both cases are microfabricated using lithography techniques. Carriages and rotors may be made out of any type of material (in the rotational case, a glass lens was used for a rotor). The work demonstrates that, for a 5-V excitation, 1.6×10^{-12} N/m/V^2 normalized torque could be achieved, as opposed to 1.4×10^{-15} N/m/V^2 for electrostatic motors operating at 100 V.

The piezoelectric effect scales down with the bulk of the material; therefore, miniaturization opportunities are limited, and hybrid-type microactuators, where larger pieces of piezoelectric material are glued onto a substrate, are sometimes more reasonable. This has been the approach followed, for example, in the fabrication of piezoelectric micropumps (see below and Figure 1.11),[55,56] linear stepper motor,[57] and microvalves.[58]

Piezoelectric Pumping

In a tube vibrating with acoustic energy, an axially directed, acoustic-streaming force is generated along the inner surface.[59] This driving force can be generated along the entire length of a narrow tube to create a distributed pump that moves fluids without an externally applied pressure. The pump surface area and the driving force per unit volume of enclosed fluid increase as the tube diameter decreases

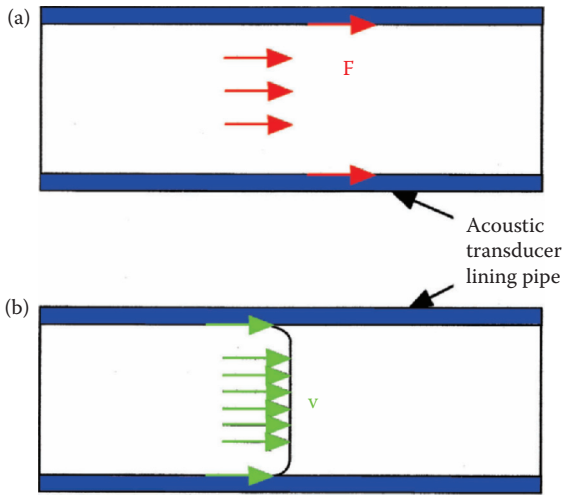

FIGURE 8.24 Acoustic streaming in a fluid inside a pipe. (a) Streaming force generated by an axially directed, traveling acoustic wave that grazes the inside walls of the tube. (b) The resulting steady state velocity distribution (blunt flow).

(pumping force $F \sim l^{-1}$). The axially directed, steady state force acting on the fluid is proportional to the square of the acoustic-wave amplitude and diminishes exponentially with distance from the wall. This force is sketched in Figure 8.24a. Because the force reaches a maximum near the walls of the tube, blunt flow is established in the fluid, as shown in Figure 8.24b, establishing an attractive technology to choose for miniaturization.

Unique properties of acoustic streaming pumps include the ability to pump without directly contacting the fluid so that a wide variety of liquids and gases may be pumped, and a simple compact structure with zero internal dead-volume. Tens of individual acoustic pumps could be operated in coordination to make an active network of interconnecting channels. One implementation of a piezopump is based on a flexural plate wave (FPW) delay line (see also Figure 8.21). An FPW device consists of a thin (~1 μm thick) membrane supported on all sides by a silicon chip. The membrane is coated with a piezoelectric film (say, ZnO) and aluminum interdigital transducers (IDTs). An RF voltage is applied to one IDT, producing mechanical stress in the piezoelectric layer, which generates flexural acoustic waves in the membrane (see Figure 8.25). The first IDT thus provides the electric field necessary to displace the substrate and form an acoustic wave. This wave propagates

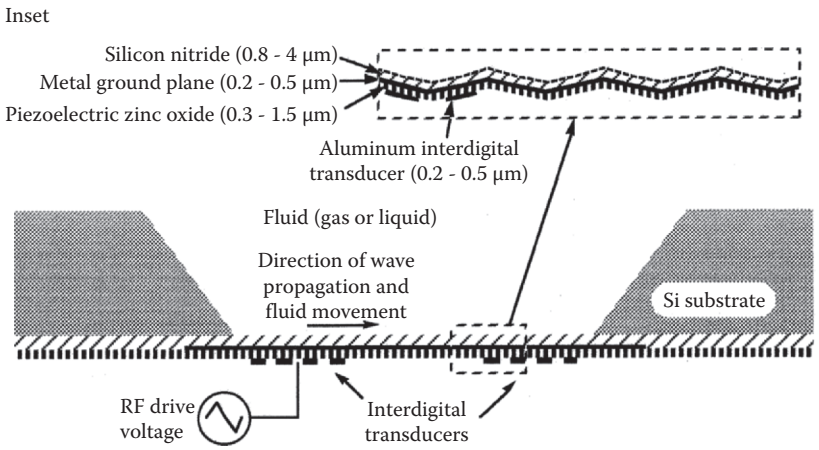

FIGURE 8.25 Micromachined flexural plate wave pump. The RF drive voltage applied to the piezoelectric interdigital transducers induces the flexural wave motion shown in the inset. Fluid motion is induced near the surface by acoustic stress. (Courtesy of Dr. R. White, University of California, Berkeley.)

through the substrate, where it is converted back to an electric field at the second IDT. Magnified, these waves look like the ripples in a flag waving in the breeze, as sketched in the inset of Figure 8.25. This wave motion induces acoustic streaming in the fluid next to the membrane. Wave propagation and fluid velocity both operate from left to right as shown in the figure. The structure generates large acoustic-wave amplitudes and is particularly effective for producing streaming; it has been proven to move air at speeds of 30 mm/s and water at 0.3 mm/s with only 5 V of RF drive.[60,61] Moroney et al. both translated and rotated small polysilicon blocks (2 μm thick and 50 μm square to 250 by 500 μm) using traveling ultrasonic flexural waves.[60] Acoustic streaming has also been established with the related SAW delay line.[62] As shown in Figure 8.20, a SAW device is fabricated by depositing interdigitated electrodes on the surface of a piezoelectric (typically $LiNbO_3$, $LiTaO_3$, and more recently also PZT thin films). An elastic wave generated at the input IDT travels along the surface and is detected by the output IDT. Besides their use for delay lines and filters in mobile phones, television and microwave communications, SAW devices have been used for many chemical sensor applications (see next) and in streaming experiments as discussed here.[63] Miyazaki et al., using a thin metal pipe flattened and bonded to a piezoelectric plate, produced a head pressure of about 10 mmH_2O and a flow rate of 0.02 cm^3/s at 40 V, peak to peak, applied to the piezoelectric ceramic plate.[62]

Acoustic Sensing of Mass

Introduction

In this section we say a few words about chemical and biological sensing by weighing with acoustic devices. Loading it directly onto a piezoelectric material can sense the mass of an analyte; alternatively, a thin layer of piezoelectric material might drive another resonator structure on which the mass accumulates as in microcantilever beams and resonator-comb drives. The main difficulty with mass sensors is achieving selectivity. In these applications, the adsorption of chemicals of interest is usually accomplished through polymer layers as sensitive coatings. One approach to improve selectivity further is to fabricate an array of sensors, each having a different partially selective film and using a pattern recognition algorithm to identify the species present (see artificial nose in Chapter 10). Another approach is to couple a front end to the sensor, such as a gas chromatograph, which separates the species and enables identification based on time of arrival at the sensor. These devices typically offer a signal-to-noise (S/N) ratio on the order of 100, with limits of detection (LOD) around 10 ppm. Mass sensitive piezotransducers used for chemical sensing are categorized by operating principle as bulk quartz resonators (BAWs), FBARs, SAW devices, FPW devices, cantilever beam resonators (see Example 8.1), and comb drive resonators.

As we saw above, all acoustic sensors will function well in gaseous or vacuum environments, but only a subset operates efficiently in contact with liquids. The shear horizontal wave does not radiate appreciable energy into liquids, allowing liquid operation without excessive damping.

Mass-Sensing BAW Devices

The mass sensitivity of a quartz crystal microbalance (QCM) or a BAW device, as derived by Sauerbrey[64] in 1959, is given by:

$$\Delta f = -\frac{2f_0^2}{A\nu_q\rho_q}\Delta m = -\frac{Cf_0^2}{A}\Delta m \qquad (8.63)$$

with:

$$C = \frac{2}{\nu_q\rho_q}$$

where Δf = frequency shift due to the added mass in hertz
C = a constant
f_0 = fundamental frequency of the oscillator in Hz
$\Delta m/A$ = surface mass loading in kg/m^2
ν_q = shear wave velocity in quartz (= 3340 ms^{-1})
ρ_q = density of quartz crystal (= 2648 kgm^{-3})

Assumptions in the derivation of this equation are that the sensor film is thin and rigidly coupled to the resonator surface, the density and acoustic properties of the film are identical to that of the quartz resonator (for very thin coatings, the influence of the coating layer on the acoustic properties is assumed to be negligible), the film is uniform and evenly coated onto the mass-sensitive electrode surface, no mechanical stress is applied to the crystal by the film, and no interfacial slip occurs at the quartz/film boundary. The equation does not apply to non-Newtonian fluids, viscoelastic films, thick films, and liquid environment. In essence, this treats any added layer on the device as being composed of quartz; that is, the new film is considered as extending the acoustic wavelength of the device. The equation predicts that the sensitivity of the BAW sensor is proportional to the square of the natural frequency. In practice, though, the natural frequency is limited since it cannot increase without decreasing the thickness of the crystal. A practical lower thickness of about 150 µm imposes a frequency upper limit of approximately 10 MHz. This frequency determines the maximum sensitivity, which based on this equation is calculated to be 0.23 kHz/µg.

In order to compare the various gravimetric sensing devices reviewed here, it is convenient to define the mass sensitivity of a sensor as follows:

$$S_m = \lim_{\Delta m \to 0} \frac{1}{f}\frac{\Delta f}{\Delta m} = \frac{1}{f}\frac{df}{dm} \qquad (8.64)$$

where Δm and dm are normalized to the active sensor area of the device. The sensitivity is thus the fractional change of the resonant frequency of the structure with addition of mass to the sensor. Another important characterization is the sensors's minimum detection limits. If the limit of mass resolution is defined as a mass sensitivity resulting in a frequency shift three times larger than the oscillator fluctuation (which is say 0.1 Hz), the minimum detectable mass density (MDMD) may be derived by rearranging Equation 8.64 as follows:

$$\Delta m_{min} = \frac{1}{S_m}\frac{\Delta f_{min}}{f} \qquad (8.65)$$

where Δm_{min} and Δf_{min} (say 0.3 Hz) are the MDMD and minimum detectable frequency change, respectively.

Based on Equation 8.64, for a thickness shear mode (TSM) device (a QCM), the theoretical sensitivity, S_m, varies as $1/\rho_q d$, where d is the device thickness. In the case of a 1-cm by 1-cm device operating at 6 MHz and with a typical thickness (d), an MDMD of 5 ng/cm^2 is calculated (Equation 8.65). This result is shown in Table 8.9.

Thin-film bulk acoustic resonators combine very high frequencies (GHz) with very thin deposited piezoelectrics (~1 µm or less). White and coworkers made an aerosol monitor using an FBAR device (see Figure 8.19) and calculated a theoretical mass limit of detection of 0.001 ng for it.[65] An FBAR is not only much more sensitive than a QCM, it is also significantly smaller.

Mass-Sensing SAW Devices

In the previous section, we saw that thinner BAW devices operate at higher frequencies and increase the mass sensitivity. However, thinning down

Table 8.9 Gravimetric Sensitivities of Acoustic Sensors

Sensor	Device Description	Theoretical Mass Sensitivity, S_m (cm^2/g)	Typical Operating frequency (MHz)	Theoretical Mass Limit of Detection (ng)	Typical Size
Thickness shear mode or quartz crystal microbalance	AT-cut quartz	$-1/\rho d$	6	5	1×1 cm
Surface acoustic wave	ST-cut quartz	$-K(\sigma)/\rho\lambda$	20–500	0.1	2×6 mm
Flexural plate wave	ZnO, SiN, Al	$-1/2\rho d$	2–5	0.002	1×6 mm
Film bulk acoustic resonator	AlN, SiN, Al, Au	$-1/\rho d$	1000–2000	0.001	100×100 μm
Microcantilever with mass loading distributed evenly over the cantilever surface		$S_m \sim 1/\rho d$	5–0.02	0.02	Micrometer-size (see Figure 8.77, where t is used for thickness)

quartz plates beyond the normal range results in fragile devices that are difficult to manufacture and to handle. For this reason, SAW devices have been investigated for gravimetry, typically operating at 100 MHz. Chemical vapor sensors based on SAW devices were first reported in 1979.[67] Most of them rely on the mass sensitivity of the detector, in conjunction with a chemically selective coating that absorbs the vapors of interest and results in an increased mass loading of the device. One disadvantage of the SAW devices is that Rayleigh waves are surface-normal waves, making them poorly suited for liquid sensing. When a SAW sensor is contacted by a liquid, the resulting compressional waves cause an excessive attenuation of the surface wave.

Often one works with two SAW devices, one of which is used as a reference, effectively minimizing the effects of temperature variations. As we saw above, SAWs are sound waves that travel parallel to the surface with their displacement amplitude decaying into the material so that they are confined to within roughly one wavelength of the surface. Interdigitated electrodes deposited on the piezoelectric material generate the acoustic waves and receive the signal. The pitch of the transducer defines the wavelength. SAW detectors, as shown in Figures 8.20 and 8.26, typically have a higher natural frequency than BAW detectors (30–500 MHz vs. a few MHz), and since signal strength is proportional to the fundamental frequency squared (Equation 8.63), they are more sensitive than quartz crystal microbalances. For the detailed derivation of the sensitivity S_m and MDMD for a SAW device, consult Ballantine et al.[63] They calculated $S_m = -K(\sigma)/\rho\lambda$, where λ is the wavelength and $K(\sigma)$ is a function of the Poisson ratio, σ. As reflected in Table 8.9, the mass sensitivity of a SAW device might be up to 50 times higher than that for a QCM, while a SAW device is typically somewhat smaller in size.

The superior sensitivity of a SAW device over a QCM may also be understood by recognizing that the sensitivity of the acoustic mass sensor is proportional to the amount of acoustic energy in the propagation path that is being perturbed. Bulk acoustic wave sensors typically disperse the energy from the sensing surface through the whole bulk of the material all the way to the other surface. This distribution of energy minimizes the energy density on the surface, which is where the sensing is done. SAW sensors, conversely, focus their energy on the surface, tending to make them more sensitive. However, SAW detectors are susceptible to changes in stiffness, dielectric constant, and relative permittivity relative to the surface mass, which can degrade sensitivity. BAW detectors have the principal advantage of negligible influences from conductivity and permittivity.

For both TSM and SAW sensors, to obtain higher sensitivity, one must increase the operating frequency.

SAW Example Application: Dew Point/Humidity Sensor

If a SAW sensor is temperature controlled and exposed to the ambient atmosphere, water will

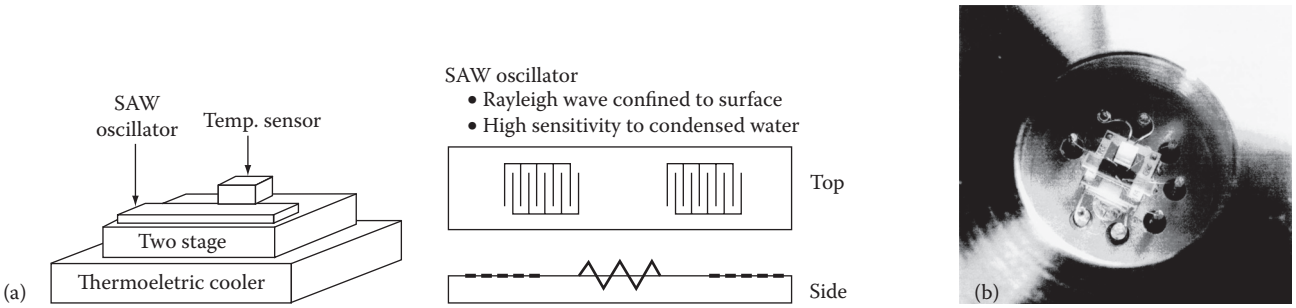

FIGURE 8.26 Surface acoustic wave (SAW) hygrometer. (a) schematic of the direct dew point sensor.[68] (Courtesy of Dr. M. Hoenk, Jet Propulsion Laboratory, Pasadena, CA.) (b) photograph of SAW hygrometer. The SAW device (long, rectangular bar) is mounted next to a platinum temperature sensor (square white package), on top of a miniature two-stage thermoelectric cooler. The device size is approximately 1 × 1 cm.

condense on it at the dew point temperature, making it an effective dew point sensor. Current commercial instruments for high-precision dew point measurements are based on optical techniques, which have cost, contamination, accuracy, sensitivity, and long-term stability issues. At Jet Propulsion Laboratory, as part of a Micro Weather Station development program, a new microhygrometer operating on accurate dew point measuring principles was demonstrated. A schematic illustrating the SAW hygrometer is shown in Figure 8.26. This device precisely measures the dew point/frost point temperature of ambient air. A quartz SAW microsensor detects the presence of thin layers of water on its surface as its temperature is varied by a miniature thermoelectric cooler. A fast digital feedback loop is used to control the sensor's temperature such that the amount of water on the sensor is held constant. This temperature is the dew point or frost point. This approach is functionally similar to the conventional chilled mirror hygrometers. However, the SAW moisture sensor provides much higher sensitivity and faster response for small amounts of water than does the optical detectors used in conventional hygrometers. This advantage, coupled with a high-performance digital feedback loop and precise measurements of the sensor temperature, enables accurate measurements with a response over an order of magnitude faster than conventional airborne hygrometers.

Mass-Sensing FPW Devices

FPW devices with sorbent polymer films respond to vapors in a manner similar to SAW devices coated with the same polymer. The FPW vapor sensor, however, is slightly smaller (see Table 8.9) and offers lower absolute noise levels and hence lower vapor detection limits. Earlier we listed other advantages associated with using an FPW or Lamb wave device for mass sensing. Lamb waves can propagate along a substrate even when immersed in water. Even though particle displacement is in the direction normal to the substrate, the low velocity of the acoustic waves preclude them from leaking into the environment. The accompanying electronics necessary for Lamb wave device applications also work at lower frequencies than those of SAW devices and are thus easier to design and cheaper to implement. Most importantly, as shown in Table 8.9, the mass sensitivity of a Lamb wave sensor is considerably greater than that of a SAW or Rayleigh wave sensor. The sensitivity calculated by Ballantine et al. for an FPW is given as $S_m \sim -1/2\rho d$.[63] In an FPW device, higher sensitivity is reached by reducing the plate thickness, d (this may be made less than a micrometer!). Mass sensitivity increases as membranes thickness decreases, and frequency decreases at the same time. This scaling law is in contrast to SAW devices, where mass sensitivity increases as frequency increases.

Acoustic Imaging

There is substantial interest in two-dimensional arrays of acoustic transducers for three-dimensional acoustic imaging. Such arrays may be used in handheld diver's sonar, medical ultrasound imaging, and

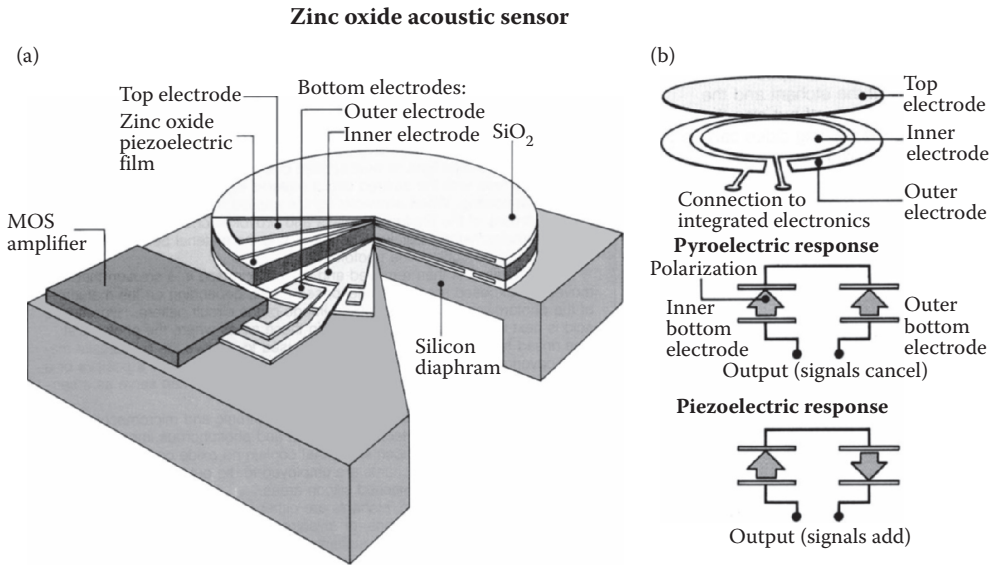

FIGURE 8.27 Zinc oxide acoustic sensor. (a) Two parallel plate electrodes in Honeywell's acoustic sensor act as capacitors. (b) Voltages due to temperature variations (pyroelectric effect) on zinc oxide film cancel, while those due to pressure add, doubling the output. (After Allen, R. 1984. Sensors in silicon. *High Technology,* September: 43–81.[70])

nondestructive testing. Bernstein et al.[69] microfabricated a 16 × 16 array of PZT pixels (3 μm thick and 0.4 × 0.4 mm each) for imaging purposes. The PZT pixels were deposited by sol-gel technology with polyimide in between the pixels. In a novel approach, the ferroelectric film was poled laterally (that is, in the plane of the deposited film) so that much larger interelectrode distances became possible. Instead of using metal electrodes on opposite sides of the thin PZT film, metal electrodes with a 30-μm spacing on the top side of the film resulted in a 30-fold increase in voltage sensitivity. With a stress applied in the same direction as the poling, there was a further gain of a factor of 2 due to a higher ferroelectric coupling constant in that direction. In total, a 30 dB improved sensitivity, compared with conventional polarizing across the thickness of the PZT film, was measured.[69] A commercially available acoustic sensor from Honeywell Corporation is shown in Figure 8.27.[70] The microphone chip illustrated incorporates ZnO deposited on a silicon substrate. A unique annular electrode design permits the parasitic signal in the zinc oxide film to be canceled because of temperature variations while doubling the output because of pressure (see Figure 8.27b).

Cast or spun-on and poled polymeric films of PVDF can also be employed to integrate piezoelectrics inexpensively into silicon micromachines. Gluing of commercial PVDF film with a urethane adhesive also works. Kolesar and Dyson,[71] for example, realized a two-dimensional electrically multiplexed tactile sensor this way. A 40-μm-thick PVDF film was glued onto an 8 × 8 array of taxel electrodes (400 × 400 μm each) electrically coupled to a set of sixty-four MOSFET amplifiers located around the periphery of this array. The response of the tactile sensor was found to be linear for loads between 0.008 and 1.35 N. Crude imaging of the applied loads also was demonstrated.

Piezoelectricity Summary

Some pros for using piezoelectricity as an actuator mechanism are high-energy density/bandwidth and lower operating voltages than electrostatics. Some cons are fabrication complexity and reproducibility of the actuator characteristics, and at the microscale, piezoelectrics provide very limited strain/displacement.

In Table 8.10 (see also Figure 8.14) we summarize some of the salient points associated with piezoelectric actuators.

Dielectric Induction

In the case of dielectric induction effects on particles in liquids and on fluids themselves, one speaks about

Table 8.10 Salient Features of Piezoelectric Actuators

1. Stroke: small, 10–2 μm
2. Speed: >100 kHz (see Figure 8.14)
3. Force density: low (see Figure 8.14)
4. Complex to fabricate
5. Voltage: ~10–100 V
6. Footprint: 1–10 μm
7. Maximum energy density, U_m (in J/m³): 52 × 106 Jm^{-3}

dielectrophoresis and EHD, respectively. The word *dielectrophoresis* implies the movement of particles through induction, while in *electrohydrodynamics* the emphasis is on the movement of the fluid itself. In dielectrophoresis, the induced charges can be attractive or repulsive with respect to the inducing field, depending on the dielectric constants of the particle and the medium in which the particle is embedded. This principle can be used for sorting, moving, and separating small objects such as biological cells.[72–74] The phenomenon is detailed in Volume I, Chapter 6, on fluidics.

In EHD pumping, fluid forces are generated by the interaction of electric fields and charges in the fluid. In such pumps electrodes are regularly spaced along a microchannel and each electrode is phase shifted with respect to the next. In contrast to forces generated by mechanical pumping using an impeller or bellows, EHD pumping requires no moving parts.[75–77] The interaction of electrical fields with induced electrical charge in the fluid yields a force that then transfers momentum to the fluid.[78] The EHD effect has also been put to use in mixing of fluids of different conductivities. Choi mixed DI water and saline solution in a 10-pL volume this way.[79] Surface charges induced at the interface of the two liquid streams react with the applied electric fields to generate shear forces leading to rapid mixing of the streams passing the electrodes. Reasonable electric fields can only be built up with acceptable voltage levels within microstructures; therefore, this principle becomes more and more effective with decreasing dimensions. A requirement for the continued existence of free charge is the presence of a spatial gradient in the conductivity or permittivity. Free charge injected into a region without gradient will relax in a time characterized by the relaxation time of the charge. One way to accomplish a conductivity gradient in the bulk of a slightly conductive fluid is by imposing a temperature gradient. A limitation of EHD is its reduced effectiveness with conductive fluids, such as in biological environments.

In an induction motor, localized charges are induced in the rotor by the electrostatic field generated by the stator electrodes. Since a finite relaxation time is needed for this excess charge to be diffused, a driving torque is generated. An induction motor is driven by a traveling wave of voltage and uses charge relaxation rather than physically salient poles in a variable-capacitance motor as shown in Figure 8.6b.[80] Consequently, the rotor can be a smooth uniform plate and may even be a fluid.[81] In the case of the rotor blades, fabrication involves some rather tricky planarization steps. The conductivity of the induction motor materials, on the other hand, strongly affects performance, so fabrication difficulties associated with variable-capacitance motors with rotor blades are traded for those associated with conductivity control in induction motors.[82]

Electrostriction

Electrostriction is a property of all dielectric materials caused by the presence of randomly aligned electrical domains within the material. With an electric field applied, the opposite sides of the domains become differently charged and attract each other, reducing material thickness in the direction of the applied field (and increasing thickness in the orthogonal directions in accordance with the Poisson's ratio. The resulting strain (ratio of deformation to the original dimension) is proportional to the square of the polarization. Reversal of the electric field does not reverse the direction of the deformation. In other words, electrostrictive materials—basically all dielectrics—develop mechanical deformations when subjected to an external electrical field; that is, they show an increase in length parallel to the field. Even apparently symmetric crystals of nonconducting materials exhibit this effect, but it is usually smaller than the piezoelectric effect.[83] The phenomenon is attributed to the rotation of small electrical domains in the material upon exposure to a field. In the absence of the field,

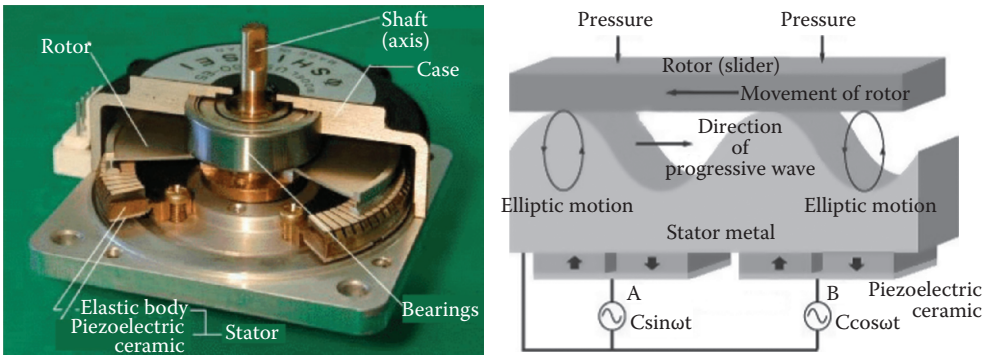

FIGURE 8.28 A ceramic piezoelectrostrictor in an ultrasonic motor. (From http://www.shinsei-motor.com/English/index.html.)

the domains are oriented randomly. The alignment of the electrical domains parallel to the electrical field results in the development of a deformation field in the electrostrictive material. Usually, the effect is small, but a few materials, such as certain titanates and zirconates, show a large effect, in which case they are ferroelectric and exhibit properties analogous to ferromagnetic materials. In both groups of materials, spontaneous polarization occurs within small regions or domains. The electric dipoles in ferroelectric materials or the elementary magnets in ferromagnetic materials are in parallel alignment within each domain. Like piezoelectrics, electrostrictors are often based on the perovskite crystal structure. Two examples of electrostrictive materials are barium titanate and lead magnesium niobate (PMN).[32,33] In the case of PMN, electrostriction gives rise to a mechanical deformation comparable to that induced by the piezoelectric effect in PZT. Fripp and Hagood compared the relative merits of piezoceramics and electrostrictors for vibration suppression.[83] Uchino made astronomy mirrors, the shape of which is continuously adjustable by bonding silvered glass to a series of electrostrictive layers that enable one to make minute adjustments to the mirror's shape in response to an applied field.[84]

A ceramic piezoelectrostrictor is used in the motor shown in Figure 8.28. This ultrasonic motor uses ultrasonic vibration (20 kHz or above) as the driving source and comprises a stator (a piezoelectrostrictor ceramic glued to a metal as the elastic body) and a rotor (the dynamic body). The piezoelectrostrictor ceramic is glued onto one side of the metal stator. The rotor is pressed against the opposite stator metal surface. Comb tooth-shaped grooves are created on the metal stator surface facing the rotor. The rotor is pressed tightly against this comb-toothed side of the stator metal surface. The ceramic element generates ultrasonic vibration when a specific high-frequency voltage is applied and the piezoelectric ceramic itself is expanding and contracting. The ultrasonic wave, i.e., swelling and falling of the stator surface, travels along the surface of the stator in a single direction. The ultrasonic vibration that travels in this manner is called the *progressive wave*. The comb tooth-shaped grooves on the stator surface are devised to make the amplitude of the elliptic motion large and to reduce abrasion. As the progressive wave travels and undulates through the contact, an elliptic motion is generated. The locus of the elliptic motion points in the opposite direction of the progressive wave traveling on the stator surface.

Pyroelectricity

The spontaneous polarization in ferrorelectrics is temperature sensitive. This is called the *pyroelectric effect*, which was discovered in tourmaline [(Na,Ca)(Li,Mg,Al)(Al,Fe,Mn)$_6$ (BO_3)$_3$ (Si_6O_{18})(OH_4)], the so-called *Ceylon magnet* (class 3m) by Teophrast in 314 BC and first recorded in the scientific literature in 1824 by Brewster.[32,85] The word is derived from the Greek for "heat electricity" and is the development of electric polarization in classes of noncentrosymmetric crystals subjected to a temperature change. Electrical polarity in a biological material is produced by a change in temperature. Pyroelectricity is probably a basic physical property of all living organisms. First discovered in 1966 in

tendon and bone, it has since been shown to exist in most animal and plant tissues and in individual cells. Pyroelectricity appears to play a fundamental part in the growth processes (morphogenesis) and in physiological functions (such as sensory perception) of organisms. From Volume I, Chapter 2, we know that there are twenty-one classes lacking a center of symmetry: 1, 2, m, 2mm, 222, 3, 3mm, 32, 4, –4, 4mm, –42m, 422, 6, –6, 6mm, 62m, 622, 23, 43m, and 432. Among materials electrically polarized because of crystal structure, pyroelectric materials are such that they become electrically polarized with changes in temperature, and the amount of electric charge produced varies according to temperature change. The phenomenon is present in crystallized dielectrics with one or more polar axes of symmetry. In polar crystals, the centroids of positive and negative charges in a unit cell do not coincide. As a result, nonzero polarization, *P*, of the crystal occurs. Pyroelectricity is thus only possible in crystals lacking a center of symmetry and also have a unique polar axis: 1, 2, m, 2mm, 3, 3mm, 4, 4mm, 6, and 6mm. The polarization, *P*, of the crystal changes with temperature, and this is the result of a structure change with temperature. While all pyroelectric materials are piezoelectric, the opposite is not true; for example, quartz is piezoelectric but not pyroelectric. Both zinc oxide, with its wurtzite crystal structure, and PZT, with a ferroelectric perovskite structure, feature an intrinsic dipole moment and show pyroelectricity even in thin film form. In Volume I, Figure 2.10, we already illustrated the pyroelectric effect in $BaTiO_3$. The strongest pyroelectric effect for a thin film is measured with the sol-gel processed tetragonal $PbTiO_3$.[48,86] The pyroelectric constant, *p*, of these materials is defined as the differential change in polarization with temperature in the case of uniform heating, constant stress (σ), and low electric field (*E*) in the crystal (see also row 1 in Volume I, Table 2.1):

$$p = \left(\frac{\partial P}{\partial T}\right)_{\sigma,E=0} \tag{8.66}$$

p is expressed in C/cm^2 K. Thin films of ZnO, PZT, and $PbTiO_3$ all show pyroelectric coefficients similar to the bulk material: $0.95–1.05 \times 10^{-9}$ C/cm^2 K for ZnO, $50–70 \times 10^{-9}$ for PZT, and $95–125 \times 10^{-9}$ for $PbTiO_3$.[48,86]

In the pyroelectric IR (for 10 μm) sensor configuration shown in Figure 8.29a, two sensing elements are connected in electrical opposition and one is shielded from the radiation source, to cancel out the effect of any drift in ambient temperature. A germanium window is used because it is opaque to visible light but transparent at wavelengths near 10 μm. In Figure 8.29b, a sensor IR array that was developed in the 1980s is shown. Detector elements made of lead strontium titanate (PST) or barium strontium titanate (BST) were commonly used. These materials have Curie temperatures close to room temperature. The devices operate at temperatures above the Curie level (in the so-called *paraelectric phase*), and an applied electric field induces the pyroelectric effect. Laser-assisted chemical etching produces an array with a large number of detector pixels. The elements on that array are soldered (or "bump bonded") to a silicon multiplexer. Contemporary versions have as many as 384 × 288 pixels, and a noise-equivalent temperature difference (NETD) is a measure of the detector-noise-limited sensitivity of single-band IR systems) as low as 75 mK. Micromachined thin-film elements with even lower NETDs are under development.

Single crystals of triglycine sulfate (TSG), $LiTaO_3$, and $(Sr,Ba)Nb_2O_6$ are widely used for heat-sensing applications. Using $LiTaO_3$, Hsieh et al.[87] produced sensitive, wide-range anemometers. In all thermal anemometers, the goal is to measure heat loss. Usually, this is accomplished by measuring the resistance of a temperature-sensitive resistor; but with a pyroelectric sensor, heat loss generates a current directly. Gas flows of 0.1 mL/min to over 20 L/min were detected. It should be remembered that only changing temperatures can be detected this way. For a crystal maintained at a constant temperature, the charges will decay rapidly.

Using a thin (<5 μm), freestanding membrane of poly(vinylidene fluoride-trifluoroethylene) [P(VDF/TrFE)] copolymer in a Si frame, Zavracky et al. made a pyroelectric IR detector array.[88] The freestanding film is provided with top and bottom semitransparent Cr/Au electrodes, and incident IR light produces a voltage between these electrodes. The advantage of

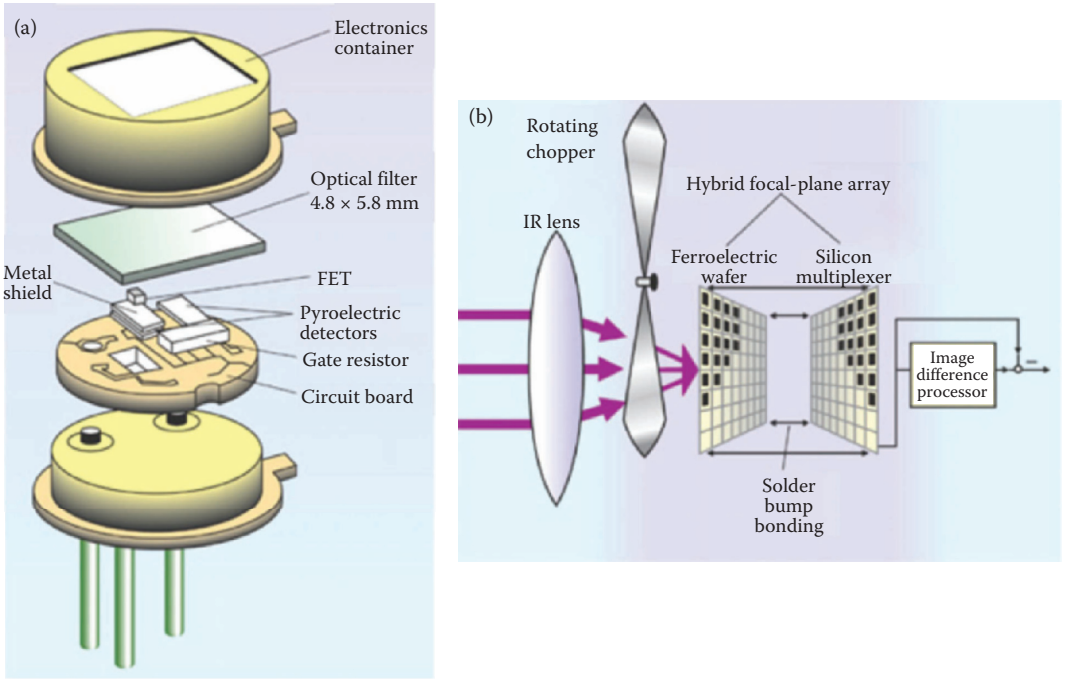

FIGURE 8.29 Single- and multiple-element pyroelectric detectors. (a) In this single-element configuration intended to monitor radiation with a wavelength near 10 μm, two lead titanate pyroelectric elements are used. One detector element is exposed to incoming radiation, another shielded under a metal strip. Both crystals are electrically connected with opposite polarities, to cancel out the effect of any drift in ambient temperature. (b) A ferroelectric-hybrid focal-plane device comprises a lens, usually made of germanium to block visible light, and an array of individual ferroelectric elements, each of which is bonded by tiny balls of solder to elements from a silicon multiplexer. The incident infrared radiation must be periodically blocked, here by a chopper, to ensure that a temperature variation is measured. (From http://www.physicstoday.org/vol-58/iss-8/p31.html.)

this polymeric pyroelectric is that it is well suited for microfabrication, since it can be applied to a substrate by spin on from a solvent-based precursor. Complementary metal-oxide-silicon (CMOS) devices fabricated in the Si frame can be used for amplification and signal processing. To prevent thermal conduction from the sensing film to the substrate, which limits sensitivity, the thin polymer film may be supported by a thin silicon nitride film.

Pyroelectric materials are used in remote control devices, night vision, and thermal sensors.

Thermoelectricity*

Introduction

Thermoelectricity covers three separate phenomena: the Seebeck effect, the Peltier effect, and the Thomson effect. The Seebeck phenomenon, discovered by the Estonian-German physicist Seebeck in 1821, is perhaps the best known, since it is used in thermocouples for the measurement of temperature differences. The effect is that a voltage is created in the presence of a temperature difference between two different metals or semiconductors. The measured voltage is proportional to the temperature difference, and the proportionality constant is known as the *Seebeck coefficient*, *S*.

Independently, the French physicist Peltier discovered the reverse effect, i.e., a current flow across a junction results into heating or cooling. In the absence of a magnetic field, the Seebeck and Peltier effects are the two most important thermoelectric effects.

The Thomson effect is the heating or cooling of a current-carrying conductor with a temperature gradient. Any current-carrying conductor (except for a superconductor) with a temperature difference between two points either absorbs or emits heat,

* Thermoelectric actuators could equally well be discussed under thermal actuators.

depending on the material. The Thomson effect was predicted and experimentally observed by William Thomson (Lord Kelvin) in 1851. The Seebeck effect constitutes a combination of the Peltier and Thomson effects. The Thomson effect is unique among the three main thermoelectric phenomena because it features the only thermoelectric coefficient directly measurable on an individual material. The Peltier and Seebeck coefficients can be determined only for pairs of materials. The Joule heat generated when a voltage difference is applied across a resistor is a loss mechanism due to nonidealities; it is related to thermoelectricity, but it is not generally called a *thermoelectric effect*. The Peltier-Seebeck and Thomson effects are reversible, whereas Joule heating, because of the second law of thermodynamics, cannot be reversible.

Mechanism behind Thermoelectricity

An applied temperature difference between two different metals or semiconductors causes charge carriers, electrons or holes, to diffuse from the hot side to the cold side, similar to the way a classical gas expands when heated. The diffusing charges are scattered by impurities, imperfections, and lattice vibrations (phonons), and since scattering is energy dependent, the hot and cold carriers diffuse at different rates. This creates a higher density of carriers at one end of the material, and the separation of charges creates an electric field. This electric field, however, opposes the uneven scattering of carriers, and an equilibrium is reached with the net number of carriers diffusing in one direction canceled by the net number of carriers moving in the opposite direction. This means the thermopower of a material depends strongly on impurities, imperfections, and structural changes (e.g., different dimensionalities, two-dimensional, and one-dimensional), and the thermopower of a material is a collection of several effects.

The build-up voltage causes a continuous current to flow in the conductors if they form a complete loop. This way, in a thermocouple (TC), a voltage is measured at the leads as the sum of the voltages across both legs of the device (see Figure 8.30). The thermocouple voltage is of the order of several microvolts per degree difference.

The Seebeck coefficient, S (in units of V/K), also known as the *thermopower* or *thermoelectric power*, measures the voltage or electric field induced in response to a temperature difference. If the temperature difference, ΔT, between the two ends of a material is small, then the thermopower of a material is defined as follows:

$$S = \frac{\Delta V}{\Delta T} \tag{8.67}$$

and a thermoelectric voltage ΔV is seen at the terminals. The thermopower S is an important material parameter and determines the efficiency of a thermoelectric material. A larger induced thermoelectric voltage for a given temperature gradient leads to a larger thermoelectric efficiency.

For the thermocouple in Figure 8.30, the measured electromotive force (EMF) is calculated as follows:

$$V = \int_{T_1}^{T_2} [S_A(T) - S_B(T)]dT \tag{8.68}$$

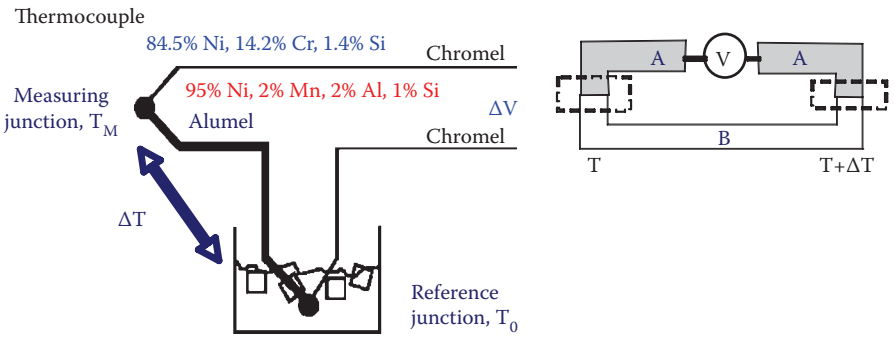

FIGURE 8.30 Thermocouple operation. Dissimilar metal junctions (at *A*/*B* and *B*/*A*) with the reference junction at T_0 (say, an ice bath) and the measuring junction at T_M, lead to a voltage reading *V*. (From a talk by Chien-Neng Liao, NTHU.)

where S_A and S_B are the Seebeck coefficients of the metals *A* and *B*, and $\Delta T = T_1 - T_2$ is the temperature differential between the two junctions. The Seebeck coefficients are nonlinear and depend on the conductors' absolute temperature, material, and molecular structure. A thermocouple can be used to measure a temperature difference directly, or to measure an absolute temperature, by setting one end to a known temperature. Several thermocouples in series are called a *thermopile*. The thermocouple can also be used to extract energy in applications where heat and temperature differences are available "for free" (see energy harvesting in Chapter 9). Thin-film thermocouples have been used, for example, to power a watch on the basis of the temperature difference between its cool front face and the warm skin contact. A disadvantage of this approach is the very low efficiency of the conversion.

Typically, a metal displays a small thermopower because it comes with half-filled bands. In contrast, semiconductors can be doped with an excess amount of electrons or holes and thus can have larger positive or negative values of the thermopower depending on the charge of the excess carriers.

The Peltier effect is illustrated in Figure 8.31. When charge carriers flow from one material into another in which their average transport energy is higher, they absorb thermal energy from the lattice, and this cools the junction between the two materials. One can think of this as the electron gas expanding in the energy space as they enter the second material. The thermoelectric process is reversible, so if the direction of the current is reversed, energy is released to the lattice, and there is heating at the junction.

The definition of the Peltier coefficient, Π_{AB}, is given as the ratio of heat absorption (J_Q) over current flow (J_E) (see Figure 8.31).

$$\Pi_{AB} = \frac{J_Q}{J_E} \tag{8.69}$$

As mentioned above, there is no direct experimental method to determine an absolute Seebeck coefficient or absolute Peltier coefficient for an individual material. However, in 1854, Thomson found two relationships, now called the *Thomson* or *Kelvin relationships*, relating the three thermoelectric coefficients. Therefore, only one can be considered unique. The absolute temperature, *T*; the Peltier coefficient, Π; and the Seebeck coefficient, *S*, are related by the first Thomson relation:

$$\Pi_{AB} = ST \tag{8.70}$$

In turn, *S* and *T* are related to the Thomson coefficient, μ, by the second Thomson relation as follows:

$$\mu = T\frac{dS}{dT} \tag{8.71}$$

The efficiency of a conventional thermoelectric cooler is controlled by a parameter *Z*, given by:

$$Z = \frac{S^2\sigma}{\kappa} \tag{8.72}$$

where σ and κ are the electrical and total thermal conductivities (with both lattice and electrons contributions) of the material, respectively, and *S* is the Seebeck coefficient (in μV/K). More commonly a *dimensionless figure of merit ZT* is defined by multiplying Z with the average temperature T. Larger values of ZT indicate a greater thermodynamic efficiency and *ZT* is a convenient figure for comparing the

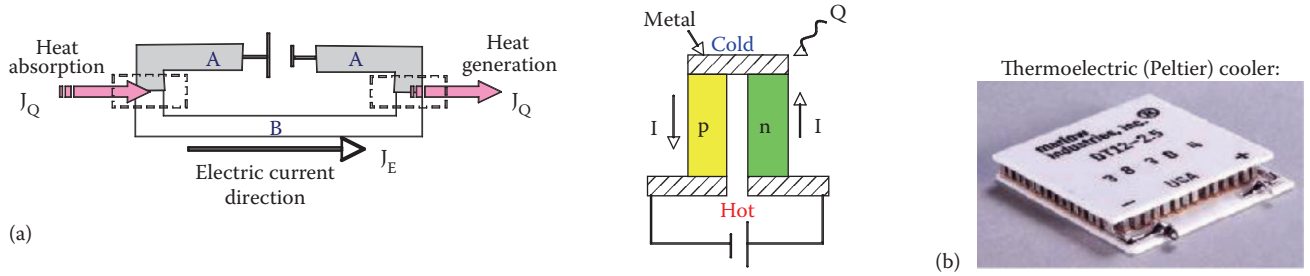

FIGURE 8.31 In a Peltier device, current flow across a junction of dissimilar metals causes a heat flux, thus cooling one side and heating the other. (a) Illustration of the Peltier effect. (b) Picture of a Peltier cooler. (From a talk by Chien-Neng Liao, NTHU.)

efficiency of devices using different materials. One can show that the efficiency for cooling, represented by Φ, and that of heating, symbolized by η, both increase with an increase of:

$$(1 + ZT)^{\frac{1}{2}} = \left(1 + \frac{S^2\sigma}{\kappa}T\right)^{\frac{1}{2}} \qquad (8.73)$$

Consequently, requirements for a good thermoelectric (TE) material are a high figure of merit (*ZT*), i.e., a high Seebeck coefficient (*S*), a high electrical conductivity (σ), and a low thermal conductivity (κ). For good thermoelectric materials one has a *ZT* of ~1, and this remained the upper limit for many years. Thermoelectric compounds include bismuth telluride (Bi_2Te_3), used for refrigeration, bismuth antimony (BiSb), lead telluride (PbTe), and silicon germanium ($Si_{1-x}Ge_x$), used for power generation. These materials today are used for smaller cooling/heating applications; they are not highly efficient but are environmentally friendly and very reliable. On a larger scale, thermoelectric refrigeration would be very interesting as it involves no toxic chlorofluorocarbons (CFCs) and no moving parts and is quick and reliable. The biggest problem is that *ZT* has to be improved from ~0.9 to 3 or higher to become more commercially attractive [*ZT* needs to improve to >1.3 at 300 K for a major impact in electronics cooling and to around 2.5 for a revolutionary impact in air conditioning and power from waste heat (energy scavenging)]. The pioneering work of Hicks and Dresselhaus in 1993 renewed interest in thermoelectrics.[89] Dresselhaus et al. showed that lower-dimensional structures such as nanowires based on bismuth, BiSb, Bi_2Te_3, and SiGe nanotechnology could lead to a higher *ZT*. This group demonstrated that electrons in low-dimensional semiconductors such as quantum wells and wires exhibit an improved thermoelectric power factor. This is due to the fact that electron motion perpendicular to the potential barrier is quantized creating sharp features in the electronic density of states (DOS). The higher density of states at the Fermi level increases σ, and the increased phonon boundary scattering lowers κ (see also Volume I, Chapter 3 and Chapter 3, this volume). Both factors contribute to make *ZT* higher. In Figure 8.32, we show the thermoelectric figure-of-merit *ZT* of a Bi quantum well and quantum wire as a function of size (see also Chapter 3, this volume).

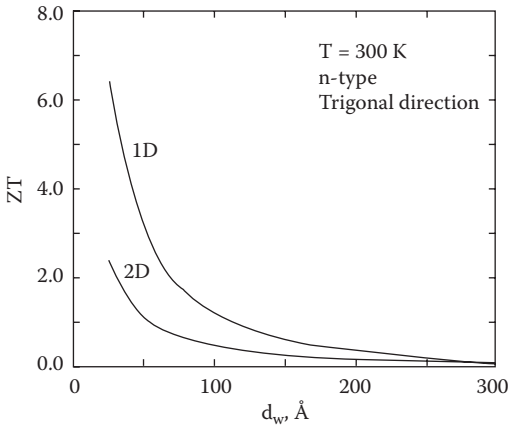

FIGURE 8.32 Thermoelectric figure of merit *ZT* of bismuth quantum well and quantum wire as a function of dimension.[89]

Because of the massive amount of processing know-how and the relatively large Seebeck coefficient, polysilicon is an attractive material for thermocouples. The Seebeck coefficient for 0.38-μm-thick n-polysilicon films with a sheet resistance of 30 Ω/□ is –100 μV/K; for n-polysilicon with a sheet resistance of 2600 Ω/□, it is –450 μV/K. For p-polysilicon with a 400 Ω/□ sheet resistance, it is 270 μV/K. Silicon might also start playing a more and more important role in heating and cooling applications. In 2008, a team from Caltech and a team from University of California, Berkeley, separately reported that they were able to increase silicon's ability to convert heat into electric current by as much as 100 times.[90,91] Bulk silicon is only an average material for thermoelectric conversion, because its thermal conductivity is too high; heat travels across it so well that it is difficult to create the necessary temperature gradient. Bulk silicon at room temperature has a *ZT* of only 0.01, but the Berkeley team increased that to 0.4, and the Caltech team increased it to 0.6. This puts silicon nanowires almost on par with bismuth telluride (see above). Making thermoelectric devices out of silicon, which is much more abundant, cheaper, and easier to handle than bismuth telluride, could help create a large market for these devices.

An excellent 2006 review on nanoscale thermal transport and microrefrigerators on a chip is by Dr. Ali Shakouri.[92]

Electrets

A permanently charged dielectric, an electret, forms an elegant base to improve upon electrostatic actuation by setting up a permanent electric field, thereby reducing or eliminating the need for a large applied bias. There are many different methods to form electrets from high-impedance dielectrics, such as the corona, the liquid contact, and the electron beam methods.[93,94] An electret-based micromachine may incorporate a capacitor charged because of the presence of the electret between the capacitor plates while one of the plates is sensitive to an external force (e.g., pressure). Micromachined electret microphones have been built this way and exhibit an open-circuit sensitivity of about 2.5 mV/μbar at 1 kHz.[95] By charging up SiO_2 with a 300-V corona, electrets in these subminiature microphones exhibit a charge decay time constant amounting to more than 100 years of expected operation. Similarly, an electret-based pressure sensor with a permanently charged polymer foil (commercially available Teflon FEP) as the electret has been manufactured. The foil was charged by electron beam exposure. A maximum sensitivity of 10mA/A/100 mmHg (i.e., the measured relative change of drain current), about ten times higher than the sensitivity of piezoresistive pressure sensors with comparable dimensions ($1 \times 2 \times 0.3$ mm), was determined.

Wolffenbuttel et al.[96] point out that an insulating, electret-implanted rotor circumvents two major limitations of electrostatic motors, namely, the relatively large voltages and the friction between the rotor and the stator during rotation. Replacing the polysilicon rotor in a motor as shown in Figure 8.6b allows propulsion at smaller drive voltages as well as electrostatic levitation and lateral alignment of the rotor, making it virtually contactless. Temperature and humidity sensitivity constitute two of the biggest drawbacks of employing electrets in actuators.

Earlier, we pointed out that bone has piezoelectric properties; Mascarenhas shows that bone can also be made into an electret,[97,98] and Fukada et al.[99] report that plastic electrets applied to bone produce alterations in bone growth.

Electrorheological Fluids

Introduction: Field-Responsive Fluids

Field-responsive fluids refer to colloidal dispersions whose rheological properties are modified under the influence of an external field, typically electric or magnetic. Upon application of such fields, induced dipoles in the dispersion cause the particles to form columns that align with the applied field. Field-responsive fluids are commonly classified as electrorheological (ER), magnetorheological (MR), and ferrofluids (FF). FF are a variant of MR fluids, having as main requirement particle size below 20 nm.

The idea of field-responsive fluids dates back to the eighteenth century. As early as 1779, Gowan Knight attempted to obtain a magnetic fluid by suspending iron fillings in water but the fillings would settle too quickly. In 1896, Duff[100] observed a reversible 0.5% change of viscosity in castor oil and glycerin when applying an electric field of 27 KV/cm. In 1947 Winslow discovered a similar but larger effect when dispersing fine dielectric powders in a nonconducting fluid[101] that he called *electroviscous*.[102] Later, this term was changed to *electrorheological*. A year later, Rabinow[103] published his discovery of a similar effect, but applying a magnetic field instead, giving birth to *magnetorheological fluids*. Since then, a considerable amount of research has been conducted on the topic. Many patents were filed in the 1950s, but the lack of commercial devices and probably the fact that most suspensions suffered from particle sedimentation dampened the initial enthusiasm. In the 1980s, research revived with ER fluids as the main focus since they were thought to be closer to commercial applications. This initial hunch proved to be wrong and MR fluids became the center of attention in the 1990s and eventually led to the application of MR fluids in commercial dampers, loudspeakers, and dynamic seals. Although the interest on ER fluids is still large, they have not yet been applied in commercial devices. The reasons for the switch from ER to MR devices are that the MR effect is an order of magnitude stronger than that of ER fluids and that the required magnetic field levels are easier to achieve.

Given the fact that it is easy to obtain large electric and magnetic fields in the microdomain, research on adapting ER and MR fluids to MEMS should follow soon.

Here we only discuss electrorheological fluids. MR fluids and FF are covered below, under magnetic actuators.

Electrorheological Fluids

ER fluids are a class of colloidal dispersions, usually dielectric particles in a nonconducting fluid, that exhibit large reversible changes in their viscosity or flow rate; that is, in their rheological behavior when subjected to external electrical fields (typically of 1–4 KV/mm). These changes in rheological behavior are typically manifested by a pseudo-phase change from the liquid to a viscous, semisolid, gel-like state and result in a dramatic increase in flow resistance (the viscosity might increase by several orders of magnitude). The total power required is rather low, and the response of ER fluids to an electrical stimulus is typically in the millisecond range. The electrical field induces dipoles in the particulate phase, that is, the fine dielectric powder suspended in nonconducting fluid, and forges an interaction between the individual particles. The induced dipole then aligns with the field to minimize dipole-dipole interaction energy. Eventually, columnar structures like those presented in Figure 8.33 are formed.[104,105]

Willis Winslow, who discovered and patented[101] the electrorheological phenomenon in 1947, worked with silica gel in mineral oil. More recent formulations are based on suspensions of particles of polymers or ceramic materials in silicone oil. Typical products proposed with these actuators include clutches and transmission systems, hydraulic valves, and vibration isolation systems such as engine mounts and shock absorbers. The bulk conductance of the carrier fluid can present a difficulty to power usage; true nonconducting fluids work best. Problems with separation of fluid and particles due to evaporation, sedimentation, centrifugal forces, and electrophoresis can lead to device failures. Wear due to abrasion from particles can also cause device failure. Electrorheological fluids are very temperature sensitive, and both boiling and freezing are major issues. Furthermore, ER fluids are sensitive to impurities since polarization mechanisms might be changed by them.

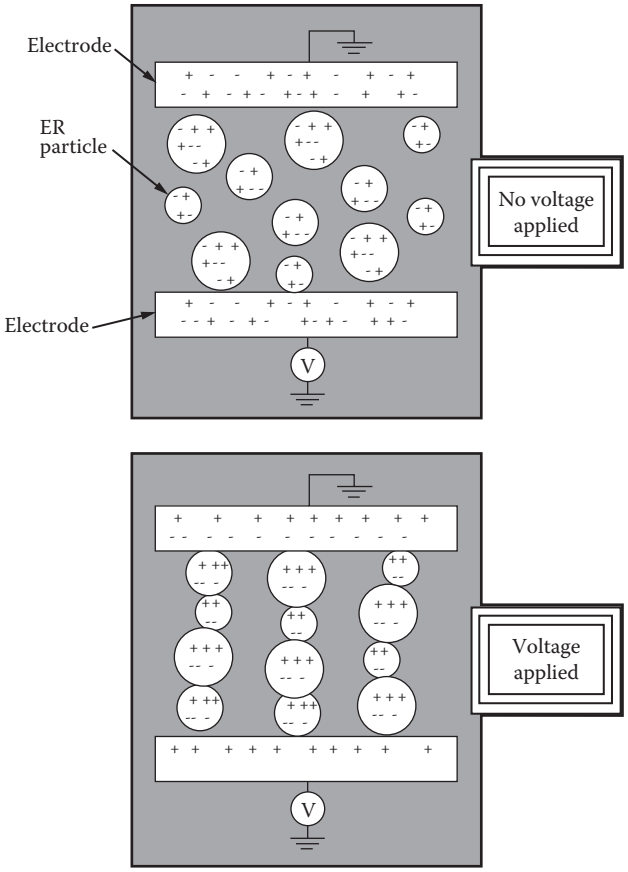

FIGURE 8.33 The electrorheological phenomenon. (After Gandhi, M.V., and B.S. Thompson. 1992. *Smart materials and structures*. London: Chapman & Hall.[32])

In 2003 a "giant electrorheological effect" was reported by Wen et al.,[106] who demonstrated an ER effect of the order of magnitude of an MR one. Electrorheological devices have not yet reached the commercial market, while MR fluids are already used in some applications (see "Magnetorheological Fluids" below).

Magnetic Actuators

Introduction

In the macroworld, electromagnetic (EM) forces dominate the development of actuators such as conventional motors. On the other hand, large electrostatic motors such as the 1889 capacitive motor made by Zipernowsky[107] are rarities rather than commodities. Because of the three-dimensional nature of magnets and solenoids, EM systems are difficult to micromachine using planar integrated

circuit (IC) processes. Electrostatic motors are simpler and more compatible with IC fabrication, and electrostatics often scale more favorably into the microdomain. These factors explain the current preponderance of electrostatic actuators in micromachining. We shall learn from a detailed comparison of electrostatic versus magnetic actuation that both present advantages and disadvantages and that both have severe problems when high-power output is demanded from the miniaturized systems in which they are embedded.

Principle behind Magnetic Actuation

A good starting point to understand magnetic actuators is Ampère's circuital law, used to calculate the magnetic field strength **H** (in A/m) around a current-carrying wire (Volume I, Figure 5.25). That law, we saw in Volume I, Chapter 5, states that the line integral of an electric current density *J* running through a straight wire generates a magnetic field strength **H** (in A/m) around that wire. The integral of **H** along the circular path *C* is equal to the current *I*, which in turn can be obtained as the integral of the current density **J** across the cross-section of the wire *S*:

$$\oint_c \mathbf{H}\cdot d\mathbf{l} = \int_s \mathbf{J}\cdot d\mathbf{s} \qquad \text{(Volume I, Equation 5.28)}$$

When applying this to a solenoid inductor as shown in Figure 8.34 one obtains the following:

$$\oint_c \mathbf{H}\cdot d\mathbf{l} = NI \tag{8.74}$$

where *N* is the number of windings in the solenoid. The electric inductance *L* (in *H*) of the solenoid equals $N\Phi/I$ (see Volume I, Table 5.1), where Φ is the magnetic flux. With $\Phi = BS = \mu HS$ (with μ the magnetic permeability and *B* the magnetic induction field) and, using Equation 8.74, we obtain:

$$\Phi = \mu\frac{NI}{1}S \tag{8.75}$$

where *l* is the length of the solenoid, so that for the inductance *L* of the solenoid we get the following:

$$L = \mu\frac{N^2}{1}S \tag{8.76}$$

We can now calculate the stored magnetic energy (U_m) and energy density (U'_m) of the solenoid. The electromotive force, or V_{EMF}, generated by the coil is given by (see also first term on the left in Equation 8.36):

$$V_{EMF} = -L\frac{dI}{dt} = -N\frac{d\Phi}{dt} \tag{8.77}$$

So that for the stored energy:

$$U_m = \int -(V_{EMF})dq = \int_0^I L\left(\frac{dI}{dt}\right)dq = \frac{1}{2}LI^2 \tag{8.78}$$

or:

$$U_m = \frac{1}{2}\mu\left(\frac{N}{1}\right)^2 S1\frac{B^2}{\mu^2(N/1)^2} = \frac{B^2}{2\mu}S1 \tag{8.79}$$

and for the energy density we divide by the volume (V = Sl) to obtain the magnetic energy density, U'_m, as follows:

$$U'_m = B^2/2\mu \tag{8.80}$$

which, in the case of an air gap, was introduced earlier as Equation 8.62, where *B* is the magnitude of the magnetic flux density in the gap and μ_0 the magnetic permeability of free space. Earlier, we also mentioned that for magnetic actuators in air, the gap energy density by pushing *B* into saturation (about 1.5 T) leads to 950,000 Jm^{-3}. The energy density stored in the rotor/stator gap for magnetic, electrostatic, piezoelectric, and SMA actuation (see below) was compared in Table 8.8.

By analogy with the electrostatic energy density from Equation 8.2:

$$U' = \frac{1}{2}\varepsilon E^2 = \frac{1}{2}\mathbf{D}\cdot\mathbf{E} \tag{8.2}$$

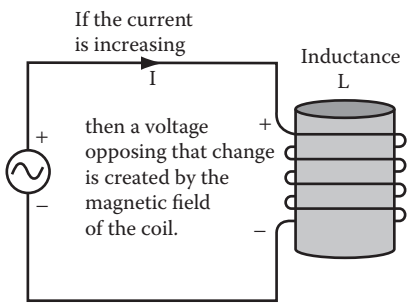

FIGURE 8.34 Solenoid inductor.

the magnetic energy density can be written out as follows:

$$U'_m = \frac{B^2}{2\mu} = \frac{1}{2}\mathbf{H}\cdot\mathbf{B} \tag{8.81}$$

And by analogy to the electrostatic surface force F, given earlier as follows:

$$F = -\nabla U \tag{8.3}$$

we calculate a translational magnetic force, F_m, as (see Figure 8.35, where translation is in the y direction):

$$F_m = -\nabla U_m \tag{8.82}$$

with:

$$U_m = \frac{1}{2}LI^2 = \frac{1}{2}\mu N^2 l S I^2 \tag{8.79}$$

we obtain for a small movement, dy:

$$dU_m = \frac{1}{2}N^2 S I^2\,[\mu(1-dy) + \mu_0 dy] \tag{8.83}$$

Or, with $\mu = \mu_0(1+\chi)$, we calculate the following for the magnetic restoring force along the y-axis:

$$F_m = \frac{dU_m}{dy} = -\frac{1}{2}N^2 S I^2 \mu_0 \chi \tag{8.84}$$

To garner some magnetic actuator scaling insights, we rewrite Equation 5.28 of Volume I as follows:

$$\oint_c \mathbf{B}\cdot d\mathbf{l} = \mu_0 I = \mu_0 \int_s \mathbf{J}\cdot d\mathbf{s} \tag{8.85}$$

This equation describes the creation of a magnetic field by a current, with S defining the area of the surface bounded by C, and J the current density. We use this expression for an example calculation of scaling of the solenoid shown in Figure 8.36.[108] As the system becomes smaller, area ds decreases more rapidly than dl, and B decreases unless the current density J is increased. We refer to the appendix in Trimmer[109] for a more detailed analysis. His results indicate that different assumptions about current density and heat transfer lead to different scaling laws. When the current density is kept constant and the size of the system is decreased, the force between two EM wires or coils scales as (l^4). In other words, a size reduction of 10 means a magnetic force reduction of 10,000. Electrostatic force scales as l^2, and from Chapter 7, on scaling, we remember that the lower the coefficient in l the better the scaling behavior into the microdomain. So from this vantage point, electrostatic actuators scale better than EM ones. The scaling results of the interaction between a coil and a permanent magnet are somewhat better: (l^3). To improve the situation further, we can increase the current density. The resulting heat, as we will see below, is more effectively removed from microstructures, thus avoiding overheating and improving the scaling. Constant heat flow per unit area of the windings results in l^3 ($l^{2.5}$ with a permanent magnet). A constant temperature difference between windings and environment yields l^2 (and also l^2 for the permanent magnet case). For the last magnetic

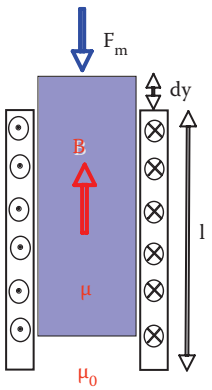

FIGURE 8.35 Magnetic force in a translational motion.

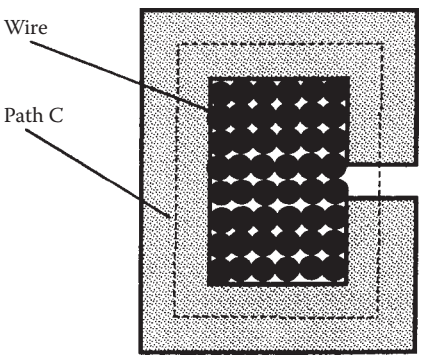

FIGURE 8.36 The line integral of B·dl over a closed curve C is equal to μ_0, the magnetic permeability of free space times the current through this loop C. As the system becomes smaller, the area decreases more rapidly than the length of the dashed line. [After Trimmer, T. 1990. In *Proceedings, Integrated Micro-Motion Systems: Micromachining, Control, and Applications (3rd Toyota Conference),* 1–15. Aichi, Japan.[108]]

case, where the force scales as (l^2), the power that must be dissipated per unit volume scales as (l^{-1}), or, when the scale is decreased by a factor of 10, 10 times as much power must be dissipated. The use of superconductors could eliminate this problem (see below).

Examples of Magnetic Actuators

Introduction

The magnetic actuation examples we consider here are magnetic levitation for making valves, magnetic micromotors, and a bead array counter (BARC).

Levitation Valve

Friction and wear in miniaturized systems primarily relate to the surface contact between solids, in particular in bearing surfaces supporting the load of the micromachinery. They scale as l^2 and become increasingly important in the microdomain (see also Chapter 7). The friction in early electrostatic micromotors was actually found to be comparable to the friction of brake materials on cast iron.[110] Levitation eliminates wear and friction, two factors affecting reliability and control. Levitation is obtained from magnetic,[111] electrostatic,[112,113] and fluidic forces.[114] Here, we consider magnetic levitation for making a valve.

Levitation with magnetic devices, or *maglev*, can be achieved by various methods, such as with permanent magnets, electromagnets (including superconducting magnets), and diamagnetic bodies. Working with permanent magnets leads to better scaling behavior than working with electromagnets (see above). Wagner et al.[115] levitated a small, rare-earth permanent magnet out of the plane of a silicon substrate equipped with a planar coil as shown in Figure 8.37b. This moving structure may be used to close off a hole in a valve seat, making for a magnetically actuated valve. The permanent magnet was glued onto a silicon micromachined thin plate suspended by a thin silicon spring made from suspending beams parallel to the substrate edge. The monolithically integrated seventeen-turn planar coil was used to generate a magnetic field force, which forces the magnet on its spring suspended platform

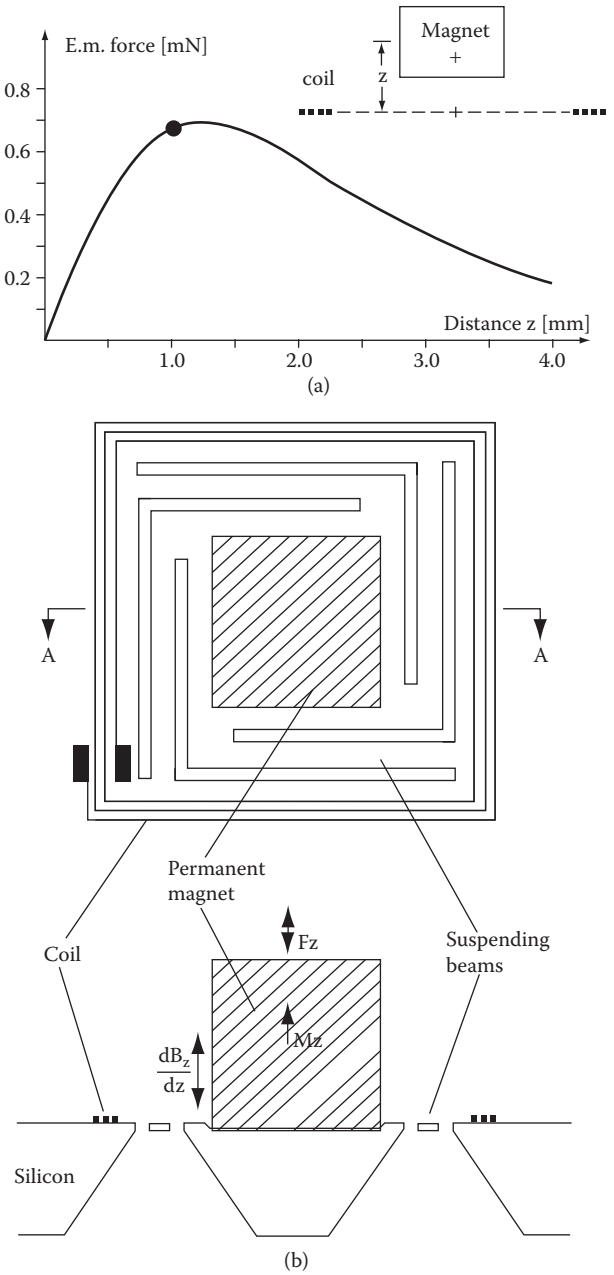

FIGURE 8.37 Magnetic actuator. (a) Electromagnetic force on a magnet. The dot indicates the magnet position in the fabricated device. (b) Schematic of a vertical magnetic microactuator with integrated planar coil and hybrid-mounted permanent magnet. [After Benecke, W. 1991. Silicon-microactuators: Activation mechanisms and scaling problems. In *1991 International Conference on Solid-State Sensors and Actuators (Transducers '91)*, 46–50. San Francisco, CA.[116]]

to move vertically (z-direction).[116] Using planar IC technologies to manufacture the coil ensures an optimum heat flow within the device (see below under Thermal Actuators). If μ_z, the magnetization of the permanent magnet, is independent of the magnetic

induction field, B, the vertical force acting on the permanent magnet is given by the following:

$$F_{m,z} = \mu_z \int \frac{dB_z}{dz}\, dV \tag{8.86}$$

where B_z represents the vertical component of the magnetic field produced by the planar coil. The magnetic force is proportional to the volume of the magnet. Thin magnetic layers will, in general, be insufficient to generate high forces. Problems with commercially available NdFeB permanent magnets include the fact that these magnets, like other rare-earth-based magnets, incorporate on their side (nonpole) surfaces a magnetically reversed layer of about 20 µm thick. This surface demagnetization limits the miniaturization of these permanent magnets to a few hundred micrometers; the smallest commercially available size is about 0.3 mm. The deflection of the highlighted actuator is given by Hooke's law as follows:

$$\Delta z = \frac{F_{m,z}}{k} \tag{8.87}$$

with k symbolizing the spring constant. The magnitude of the magnetic field depends on the current density achieved in the windings generating the field, and this current in turn is limited by heating of the solenoid metal (gold, in this case). Sheet resistance of thin-film conductors, electromigration, and thermal and geometric constraints all conspire to reduce the achievable magnetic energy density. Wagner et al.[115,117] assume constant current and very efficient power dissipation and derive a magnetic force with quadratic scaling and a deflection exhibiting linear scaling. To obtain constant current, this group has the number of coil turns scaling linearly with the cross-section of the coil wire. Quadratic force scaling, also found for electrostatics, lends itself well to the microrange. In practice, the magnetic force in the example increases rapidly at first and then decreases slowly with z, exhibiting a maximum value of 0.68 mN at a distance of 1.25 mm from the coil plane (see Figure 8.37a).[116] Increasing the volume of the permanent magnet thus works only up to a point, as the magnetic field decreases slowly with z. For a driving current range between –300 and +300 mA, an elevation of the permanent magnet of 143 µm is achieved, resulting in a mean slope of 24 µm per 100 mA. This example indicates that at least for linear actuators, magnetic actuation can be designed to scale as well as electrostatics and that these actuators are not too hard to implement when allowing for some final manual assembly.

Along the same lines, a meso (intermediate) scale, electromagnetically actuated, normally closed valve was realized using low-temperature cofired ceramic (LTCC) tape technology by Gongora-Rubio et al.[118] In this hybrid device, LTCC green tape technology is used for the electromagnet [several layers of planar silver spirals on alumina (Dupont 951 series)] and for the fluid manifold (alumina) fabricated at the same time. Anisotropically etched Si is employed for the planar rectangular spring (similar to the Benecke spring in Figure 8.37b) and a high-energy SmCo for the mini-permanent magnet. Using a 900-Gauss SmCo (1-mm diameter) magnet, a 200-µm deflection of the rectangular planar Si spring was obtained. The square spiral spring is covered with a polysiloxane film; the rectangular spring butts up against a polysiloxane valve seat on the ceramic coil stack and is lifted of the valve seat when powered up.

Magnetic Micromotors

Electromagnetic (EM) microactuators with glued magnets of millimeter dimensions have been used for different types of vertical, torsional, and multiaxial actuation. Here we consider EM micromotors and compare them with electrostatic micromotors.

Making micromotors has fascinated the MEMS community from day one. To witness, on November 28, 1960, William McLellan collected $1000 from Richard Feynman for having made the first operating electric motor only 1/64 inch in size.[119] The handmade motor was a more or less standard, two-phase, permanent-magnet motor.

Actuators in general, we remarked earlier, often do not scale advantageously in the microdomain. The torque of both electrostatic and electromagnetic motors depends on the shearing stress on the rotor integrated over its whole area, and force production is proportional to changes in the stored energy in the gap between rotor and stator (see Equation 8.82). The amount of force that may be generated per unit

substrate area is thus proportional to the height of the motor. Large-aspect ratio rotor structures are therefore desired for both types of motors (or actuators in general for that matter). Torque is a volume effect, and small, flat-surfaced micromachined micromotors have a only a small force available for actuation. For most practical applications, motors with torques larger than 10^{-6} to 10^{-7} Nm are required,* but, as we saw above, the torque generated with a typical surface-micromachined electrostatic motor is only in the nano-newton-meter or pico-newton-meter range (see Figure 8.6b for a typical surface micromachined motor). In practice, the performance with respect to torque and speed of a traditional miniature magnetic motor with a 1-mm diameter to 2-mm-long permanent magnetic rotor is incomparably better than the surface micromachined motors described here and in Volume II, Chapter 7.[120]

With LIGA (see Volume II, Chapter 10) or a combination of LIGA (or pseudo-LIGA) and precision engineering, large aspect ratio magnetic motors can be built that do produce torques that are in the 10^{-6} to 10^{-7} Nm range. As an example, in Figure 8.38 we show one of the best-performing micromotors, fabricated using the sacrificial LIGA process in combination with traditional precision machining. Essentially, a permanent magnetic rotor follows a rotating magnetic field in the stator coils. Both rotor and stator in this micromotor are made from pure nickel. Such a motor with a diameter of 285 μm operates at speeds slightly above 30,000 rpm, with a current excitation level of 600 mA. No evidence of deterioration was evident even after 50 million rotations.[121] The motor manufacture illustrated here shows how LIGA micromachining and precision engineering constitute complementary techniques for producing individual parts that are then assembled afterward. Only components with the smallest features are produced by LIGA; other parts are produced by traditional precision mechanical methods. The cost of producing monolithic magnetic LIGA micromotors urges one to investigate less expensive LIGA-like technologies or

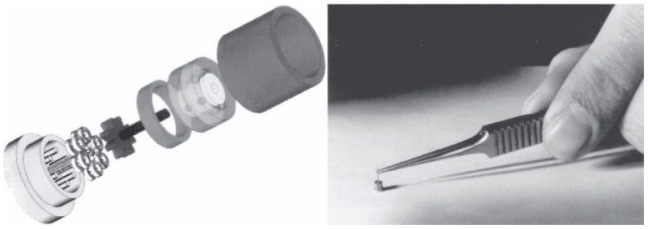

FIGURE 8.38 Large-aspect-ratio magnetic motor. (Courtesy of IMM, Germany.)

hybrid approaches (LIGA combined with traditional machining) as more accessible and adequate alternatives.

A University of Wisconsin team[122] demonstrated a series of magnetic LIGA motors, typically consisting of a plated nickel rotor that is free to rotate about a fixed shaft. Some of the motors made by this group can also be run electrostatically. Given their dramatically increased torque, these motors are again much better than their similar sized surface micromachined cousins. Using a pseudo-LIGA approach, Ahn et al. made a meander-type induction coil involving polyimide and electroplated high-permeability Ni (81%)-Fe (19%).[123] An EM motor based on this approach rotated at speeds up to 500 rpm with applied currents of 300–500 mA and a driving voltage of less than 1 V. The torque predicted for a stator current of 500 mA was 1.2 μN.

High-aspect-ratio techniques, we pointed out, also benefit torques in electrostatic micromotors. Wallrabe et al.,[124] for example, present design rules and tests of electrostatic LIGA micromotors. Minimum driving voltages needed were measured to be about 60 V and optimized designs are expected to deliver torques in the micro-newton-meter range. Suppose now that we use the same high-aspect-ratio machining techniques for both magnetic and electric micromotors, which one is then expected to be the best? For this we turn our attention again to the maximum energy density achievable in the stator-rotor gap. In conventional motors using iron, magnetic induction is limited to 1.5 T because of saturation, producing an energy density of about 9×10^5 Jm^{-3}. This is already more than twice the achievable electrostatic energy in a 1-μm gap (see Table 8.8). Moreover, it is important to remember that, in the case of electrostatic motors, there is little room for improvement, since the electrostatic

* As a reference point, to drive a cylindrical load of several hundred microns in diameter and several mm long, the required torque is of the order of 10^{-5} Nm.

energy density assumed above is close to what is achievable in vacuum. In contrast, there is plenty of room for improvement in magnetic energy density. Thin ferromagnetic films have yielded 2-T fields, and substantially higher fields are generated, at much larger expense, using superconductors (see below).[125] For example, using small-bore 10–15-T superconducting magnets, the achieved energy density of $4–9 \times 10^7$ J m^{-3} is roughly two orders of magnitude larger than the highest possible electric field density. For now, though, the 10–15-T superconducting magnets fall outside the realm of micromachining.

The efficiency—the ratio of power used in performing a desired task to the total amount of power consumed for a current-driven magnetic motor—will be worse than for a voltage-driven electrostatic device. However, Busch-Vishniac argues, since friction in small gaps, rather than electrical losses, are the major losses in microactuators, mechanical losses render nearly all types equally inefficient.[125] Moreover, since the gap in magnetics may be larger, friction is actually easier to avoid in magnetic actuators. One could add that a wider separation gap would also make the actuator less sensitive to dust and humidity.

In addition to the problem of minuscule amounts of power being produced by minuscule motors of both types, that of heat dissipation in a micromotor below a certain size needs to be solved. Busch-Vishniac calculated that a generic problem of heat dissipation exists if microfabricated microactuators continue to shrink in size without a concomitant reduction in the amount of power used in the system. For instance, a motor dissipating 100 mW should not have a rotor smaller than 20 μm, as the temperature might rise above 250°C, resulting in thermal breakdown of the metals in the microstructure. Classical models for heat convection were used to reach this conclusion. A more accurate model would result in a reduction of the heat lost by convection as the effective viscosity in the gap is greater than that predicted by the classical model (see section on heat transfer in Volume I, Chapter 6). In other words, the results generated with the classical model should be viewed as a conservative approximation; real microdevices might run hotter yet.

The more immediate challenge for both types of motors, however, is in making them in batch fashion. MEMS activities in micromachined motors today have generated plenty of new insights into phenomena such as stiction, friction, and wear of various materials but have not yet produced viable, batch-produced micromotors that can compete with a proven product such as the Panasonic piezoelectric device pictured in Figure 8.23a.

The above analysis seems to put magnetic actuation at an advantage over electrostatic actuation and even suggests that micromachined actuators are not always possible or useful. We compare magnetic and electrostatic actuators in general in a separate section, "Comparing Magnetic with Electrostatic Actuation."

The Bead Array Counter

In the bead array counter (BARC), we describe the use of a magnetic field gradient to levitate and remove paramagnetic microbeads that are not specifically bound to the surface of an array of giant magnetoresistive (GMR) sensors.[126] Recent developments in thin-film magnetic technology has resulted in films that exhibit a large change in resistance in response to a magnetic field. This phenomenon is known as GMR to distinguish it from conventional anisotropic magnetoresistance (AMR). AMR resistors exhibit a change of resistance of <3%, but GMR materials achieve a change of as much as 10–20%. GMR films have two or more magnetic layers separated by a nonmagnetic layer. Because of spin-dependent scattering of the conduction electrons, the resistance is maximum when the magnetic moments of the layers are antiparallel and minimum when they are parallel.

The BARC uses molecular recognition, such as DNA hybridization, magnetic microbeads, and magnetoresistive sensors (such as giant magnetoresistive sensors or GMR sensors), and the application of a magnetic field to detect and identify binding of a molecule with a molecular receptor. In one particular embodiment, DNA probes are patterned directly above an array of GMR sensors, as shown in Figure 8.39. Sample containing complementary DNA hybridizes with the probes on the surface. Magnetic or paramagnetic beads are labeled with a binding material (e.g., streptavidin),

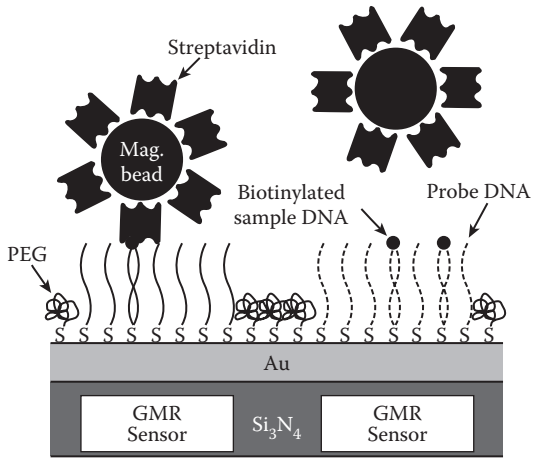

FIGURE 8.39 Schematic diagram of the bead array counter (BARC) chip surface chemistry and hybridization assay. Thiolated DNA probes are patterned onto a gold layer directly above the giant magnetoresistive (GMR) sensors on the BARC chip. Biotinylated sample DNA is then added, and it hybridizes with the DNA probes on the surface when the complementary sequence is present. Unbound sample DNA is washed away. Streptavidin-coated magnetic beads are injected over the chip surface, binding to biotinylated sample DNA hybridized on the BARC chip. Beads that are not specifically bound are removed by applying a magnetic field. Bound beads are detected by the GMR sensors. (Based on Edelstein, R.L., C.R. Tamanaha, P.E. Sheenan, M.M. Miller, D.R. Baselt, L.J. Whitman, and R.J. Colton. 2000. The BARC biosensor applied to the detection of biological warfare agents. *Biosens Bioelectron* 14:805.[126])

and they bind to biotinylated sample DNA hybridized on the BARC chip. Nonspecifically adherent microbeads are removed by means of a controlled magnetic field—applying the magnet removes >95% of these microbeads. A change in the output of the magnetic field sensors indicates the presence of magnetic particles bound to sensors and thereby indicates the presence and concentration of target molecules in the sample. The detection of the presence of beads requires a uniform magnetic field, but removing the beads requires a nonuniform large field gradient. The latter is accomplished by moving a portion of the electromagnetic core closer to the chip with a plunger.

Comparing Magnetic with Electrostatic Actuation

The debate about the relative merits of electrostatic versus magnetic actuation, especially for driving micromotors, has preoccupied many MEMS researchers over the last two decades.[119,127] Fujita and coworkers, for example, have argued that electrostatic actuation is preferred,[128–130] pointing to the following attributes of surface micromachined electrostatic actuators:

1. Thin insulating layers such as SiO_2 or Si_3N_4 exhibit breakdown strengths as high as 2 MV/cm. The power density in this field is 7×10^5 J/m^3; this value is equal to the power density of a 1.3-T magnetic field. The contracting pressure induced by this field is 1.3 MPa. A voltage of about 100 V is sufficient to generate the strong fields mentioned.
2. The electrostatic force is a surface force exhibiting a favorable scaling law. The actuation is simple, as it involves only a pair of electrodes separated by an insulator.
3. The electrostatic actuator is driven by voltage, and voltage switching is far easier and faster than current switching (as in EM actuators). Energy loss through Joule heating is also lower.
4. Weight and power consumption are low.

However, earlier, the comparison between electrostatic and magnetic micromotors demonstrated that many factors besides scaling need to be considered when deciding upon a certain type of actuation principle. Whereas in some cases, the magnetic power might scale disadvantageously into the microscale, the absolute magnetic forces achievable are much larger.

While there is some validity, especially in the case of micromotors, to the arguments favoring magnetic actuators, the criticism of micromachined electrostatic actuators is too harsh where linear micromachined electrostatic devices such as resonators are concerned. In the latter application, power output is of little concern, and these devices have found a major application, for example, in the analog devices accelerometer described in Volume II, Example 7.1. Similarly, for most optical applications such as digital mirror technology from TI (Volume II, Example 7.2), the amount of power required to deflect a laser beam with a micromachined mirror is minimal.

Table 8.11 Salient Points of Electromagnetic Actuators

1. Maximum stroke: 10^{-1} μm
2. Maximum speed: 10 kHz (see Figure 8.14)
3. Intermediate force density: 10^{-2}
4. Complex to fabricate
6. Large footprint: 1–10 mm
7. Special drive conditions: 1.5 T
8. Maximum electrostatic energy density, U'_m (in J/m^3): 9.5×10^5 Jm^{-3}

For many years, micromagnetics have found major use in Hall chips and thin-film heads for magnetic discs (see Figure 1.1d). Besides magnetic micromotors, magnetic valves, and BRAC chips, described above, micromagnetic efforts continue on making denser thin-film magnetic heads;[131] high-performance magnetographic printing heads;[132] electronic switching components;[133] different types of vertical, torsional, and multiaxial actuators;[117] and contactless magnetic transmission of force to ferrofluids (FF) (see "Ferrofluids" below).[115] The pros of magnetic actuation include high force and stroke for the size of the actuator, the ability to attract and repel, multiaxis capability, and the linear current response. The most outstanding advantage of magnetic actuators is the long range of the force. With dimensions above 1 mm and for larger forces, actuators based on permanent magnets become a good choice (see Table 8.11). The cons might be listed as large actuator footprint (approximately a centimeter), requirement of external field sources, complex microscale manufacturing/assembly processes, high-power consumption, and interactions of the magnetic field with nearby system components. Incorporating microfabrication of a permanent magnet into common MEMS fabrication processes remains an active field of research (see also Figure 8.14).

To conclude this comparison of electromagnetic versus electrostatic actuators, we summarize the key points in Table 8.12. Our conclusion regarding the status of microactuators is that electrostatics is useful in dry environments and over limited distances and that electromagnetics is still difficult to collapse into integrated structures.

Magnetostriction

Introduction

The magnetostrictive effect is the contraction or expansion of a material under the influence of a magnetic field and the inverse effect of changes in magnetization due to a stress in the material. It is the magnetic equivalent of electrostriction (see above). This bidirectional effect between the magnetic and mechanical states of a magnetostrictive or piezomagnetic material presents one with another transduction capability that can be used for building actuators and sensors. It was the Scotsman James Joule (1818–1889) who, in 1842, found that when a nickel rod is magnetized it contracts very slightly (the effect is also called the *Joule effect*). A very early use of electrostrictive materials (1861) was for the

Table 8.12 Comparison of Electrostatic versus Magnetic Actuators

	Electrostatic	Magnetic
Field energy density	4×10^5 Jm^{-3}(max)	4×10^7 Jm^{-3} (10 T)
Scaling	(l^2)	(l^3) (constant current)
Gap contamination sensitivity	Very sensitive to humidity and attracts dust	Fairly insensitive
Integrated circuit compatibility	Good	Not very good
Range	Short range	Long range
Power efficiency	Very good in the absence of mechanical friction	More power consuming even in the absence of mechanical friction
Implementation of levitation schemes	Possible	Easier implemented because larger gaps are possible
Miniaturization	Excellent	Difficult
Complexity	Low	High
Control	Voltage switching control is faster, easier to make, and more efficient	Current switching control is less efficient, more complex, and less efficient

generation of sound and ultrasound, and one of the first telephone earpieces was magnetostrictive. The magnetostrictive effect is actually familiar to all of us in the humming of transformers (expanding and contracting of the coils).

How Does Magnetostriction Work?

The magnetostrictive coefficient, ε, is the fractional change in length ($\Delta l/l$) as the magnetization of the material increases from zero to its saturation value ($\Delta l/l = \varepsilon$) (see Figure 8.40). Its value is typically in the parts-per-million range (e.g., 40×10^{-6}). It can be positive or negative in a direction parallel to the magnetic field and is independent of the direction of that field, indicating a square-law type of relationship, such as:

$$\varepsilon = \frac{\Delta 1}{1} = cB_0^2 \qquad (8.88)$$

where ε = static strain
B_0 = flux density
c (m^4Wb^{-2}) = a material constant

For a small flux density ($B \ll B_0$), taking the derivative of Equation 8.88, one derives the basic magnetostrictive strain equation:

$$\varepsilon = \beta B \qquad (8.89)$$

where $\beta = 2cB_0$ defines a magnetostrictive strain constant with dimensions of m^2Wb^{-1}. As the magnetic field, *B*, increases, the length change saturates and increasing the field strength further brings about no additional change. As in the case of piezoelectricity, the inverse effect exists as well; a changing flux density results when modulating the stress on a piezomagnet. This reverse effect is called the *Villari effect*.

The magnetostriction phenomenon is attributed to the rotations of small magnetic domains in the material, randomly orientated in the absence of a magnetic field. The orienting of these small domains by the imposition of a magnetic field results in the development of a strain field (Figure 8.41).

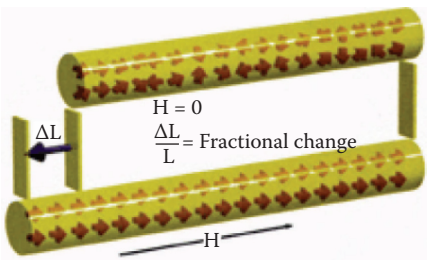

FIGURE 8.40 Magnetostrictive materials: the Joule effect.

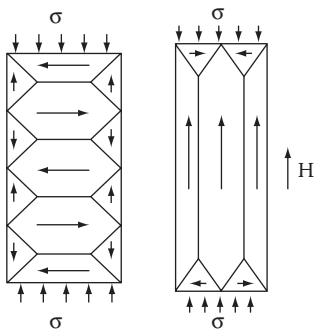

FIGURE 8.41 Magnetostriction. With a compressive load applied to a magnetostrictive material, the domain structure is oriented perpendicular to the applied force. As a magnetic field is introduced, the domain structure rotates, producing the maximum possible strain in the material.

As the intensity of the field increases, more and more domains line up with the field until saturation is reached. Magnetostrictive actuation, like piezoelectric actuation, is important when large forces must be obtained over small distances. Applications for magnetostrictive devices include high-force linear motors, positioners for adaptive optics, active vibration or noise control systems, medical and industrial ultrasonics, pumps, and sonar. Both find applications as sonar sensors, vibration dampers, and tunable-compliance materials.

The Wiedemann effect describes what happens when an axial magnetic field is applied to a magnetostrictive wire, with a current passing through it, i.e., a twisting occurs at the location of the axial magnetic field (Figure 8.42). The twisting is caused by interaction of the axial magnetic field, from an

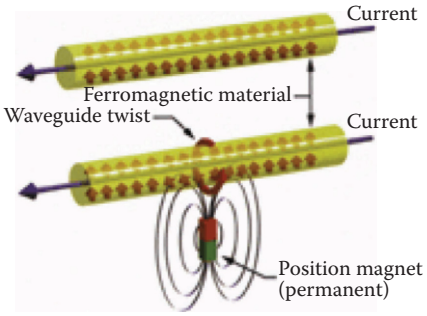

FIGURE 8.42 The Wiedemann effect: the twisting due to an axial magnetic field applied to a ferromagnetic material carrying a current.

Table 8.13 Magnetostrictive Materials with Their Magnetostrictive Coefficients

Material	Saturation Magnetostriction (μm/m)
Nickel	−28
49Co, 49Fe, 2V	−65
Iron	+5
50Ni, 50Fe	+28
87Fe,13Al	+30
95Ni, 5Fe	−35
Cobalt	−50
$CoFe_2O_4$	−250

external permanent magnet, with the magnetic field along the wire, due to the current in the wire. The inverse effect, that of creation of an axial magnetic field by a magnetostrictive material when subjected to a torque, is known as the *Matteucci effect*. Together, these effects are used in torque magnetostrictive sensors.

Magnetostrictive Materials

The amount of magnetostriction in base elements and simple alloys is small, on the order of 10^{-6} m/m. The magnetostrictive effect is exhibited by the transitional metals including iron, cobalt, and nickel and their alloys. The magnetostrictive coefficients of some magnetostrictive materials are shown in Table 8.13. The highest room temperature magnetostriction of a pure element is that of Co, which saturates at 60 microstrains.

"Giant magnetostriction" materials are materials in which the magnetostrictive coefficient exceeds 1000 μm/m (that is about two hundred times larger than that of iron). These materials are today's choice for magnetostrictive sensors and actuators. They were developed in the 1960s for underwater radar; a typical material is Terfenol-D.[104] Terfenol-D is a commercially available magnetostrictive material incorporating the rare-earth elements terbium and dysprosium ($Tb_xDy_{1-x}Fe_y$, with x between 0.27 and 0.3 and y between 1.9 and 1.98) (Etrema Company). This material offers strains up to 0.002—at liquid nitrogen temperatures (−196°C), terbium, dysprosium, and compounds of the two can exhibits strains of 0.01. The Terfenol-D effect is often referred to as the *giant magnetostrictive effect*. It works in the opposite sense of iron magnetostriction; the material expands rather than contracts. An alloy of iron with samarium also displays a giant magnetostrictive effect but, like iron, in the shrinking sense (see below and Honda et al.[134]).

Sputter-deposited magnetostrictive films present an interesting opportunity for actuation in micromachines where contactless, high-frequency operation is desired. Terbium-iron alloys are typical magnetostrictive materials that can be deposited by sputtering. Quandt et al., using an RF-sputtered TbDyFe film (10 μm thick) on a silicon cantilever 2 cm long and 50 μm thick, could deflect the silicon cantilever by more than 200 μm in an external field of only 30 mT.[135] The cantilever was operated at a frequency of 500 Hz, and no degradation could be observed after more than 10^7 operations. The same group is exploring the use of these films for valves and pumps. Honda et al. discovered that amorphous Tb-Fe films exhibit positive magnetostriction, while amorphous Sm-Fe thin films exhibit negative magnetostriction (see above), and this group built magnetostrictive bimorph cantilevers and traveling machines as illustrated in Figure 8.43a and 8.48b.[134] The actuation behavior of the magnetostrictive bimorph cantilever is as follows: a 1-cm-long polyimide beam (thicknesses of 7.5, 50, and 125 μm were experimented with) is sandwiched between an upper Tb-Fe film and a bottom Sm-Fe film, each 1 μm thick. When a magnetic field is applied along the cantilever length direction, the Tb-Fe film expands and the Sm-Fe film contracts, bending the polyimide beam downward. With a magnetic field along the width direction, the Tb-Fe film contracts and the Sm-Fe film expands, deflecting the beam upward. One version of this group's traveling machine, shown in Figure 8.43b, consists of a 7.5-μm-thick polyimide film equipped with magnetostrictive bimorph actuator layers and with two legs inclined so that it travels in one direction. With an alternating magnetic field of 100 Oe at 50 Hz applied along the machine length direction, it vibrates and travels at an average speed of 0.5 mm/s in the arrow direction.

A major application of magnetostriction is in noncontact torque sensing. An integrated silicon micromachined sensor head for torque and force measurements was first proposed in 1994 by

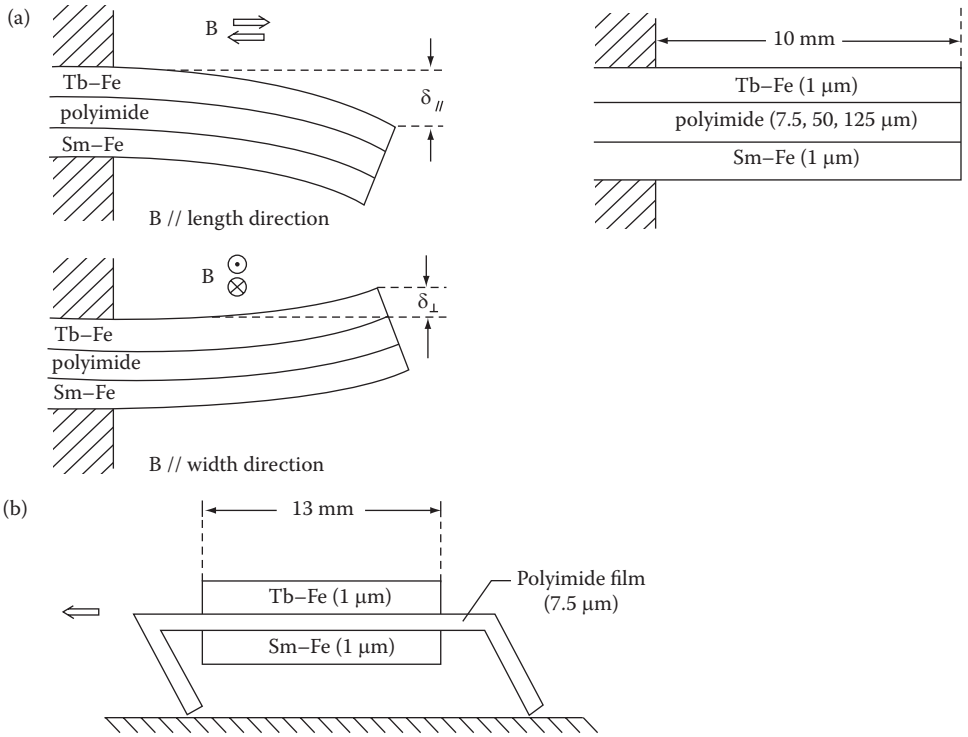

FIGURE 8.43 Magnetostrictive actuators. (a) Actuation behavior of a magnetostrictive bimorph cantilever. (b) Schematic view of traveling machine. [After Honda, T., K.I. Arai, and M. Yamaguchi. 1994. Fabrication of actuators using magnetostrictive thin films. In *IEEE International Workshop on Micro Electro Mechanical Systems (MEMS '94),* 51–56. Oiso, Japan.[134]]

Rombach and Langheinrich.[136] It is based on a magnetic yoke with an exciting and receiving coil that detects the change of permeability of a $Co_{75}Si_{15}B_{10}$ ribbon fixed to the shaft surface of an automotive vehicle. The $Co_{75}Si_{15}B_{10}$ is an amorphous metal alloy rather than the crystalline alloys discussed so far. The most common of these materials is Metglas 2605SC, an amorphous alloy of iron, with boron, silicon, and carbon [for more on these so-called *bulk metallic glasses* (BMGs), see Chapter 5]. These materials exhibit a smaller magnetostrictive distortion at saturation than do the crystalline iron-terbium alloys, and generate smaller forces, but they provide a larger response for small applied fields and vice versa—small mechanical distortions create a larger change in magnetic properties. These amorphous magnetostrictors are used in sensitive strain gauges and in accelerometers as well.[105,137]

Comparing Magnetostricion with Piezoelectrics

The power requirements for giant magnetostriction are greater than for piezoelectric materials, but the actuation offers a larger displacement, and the ratio of mass per unit stress is greater than with a PZT actuator.[138] Magnetostrictive materials have other advantages; they are metal alloys rather than brittle ceramics, and they do not exhibit dielectric breakdown under high fields as do piezoelectric and ferroelectric materials.[105] There are obviously relative advantages and disadvantages to the two technologies; some of these are listed in Table 8.14.

Magnetohydrodynamic Pumping

Magnetohydrodynamic (MHD) pumping is widely used in nuclear power plant cooling systems and has been applied for pumping and sensing of conductive gases and liquid metals.[139] It has not been exploited much in the microdomain.

MHD pumping, like EHD pumping, involves no moving parts, has a continuous flow, and is compatible with solutions containing biological specimens—both phenomena are attractive as scales go down. A MEMS MHD pump is schematically illustrated in Figure 8.44. The effect is based on the Lorentz force, F_L (see Volume I,

Table 8.14 Comparison of Magnetostrictive and Piezoelectric Materials

Parameter	Magnetostrictive	Piezoelectric
Frequency range (ultrasonic range is from 20 to 200 kHz)	<20 kHz More limited because of size	20–200 kHz Most versatile
Audible noise	More noise	Less noisy; higher-frequency piezoelectric equipment is easier brought under Occupational Safety and Health Administration (OSHA) limits by appropriate design and acoustic shielding
Power requirements	Larger	Lower
Displacement	Larger	Lower
Transducer reliability	Both are mature, highly reliable, engineered devices	
Generator reliability	2-year warranty	1-year warranty
Effect of aging; the electrical activity of piezoelectric materials slowly degrades as a half-life function from the time they are "poled" material during manufacture	No depolarization problem	In the case of piezoelectric materials, the reduction in activity after 100 days brings the activity level to within 1% of the ultimate level it will achieve over the next 17 years of aging
Energy efficiency	<50%: magnetic systems are usually less than 50% efficient because of the energy lost in heating of the coils and the effects of magnetic hysteresis	>70%: piezoelectric transducers are extremely efficient because of the direct conversion of electrical to mechanical energy in a single step
Material strengths	Magnetostrictors are metal alloys rather than brittle ceramics, and they do not exhibit dielectric breakdown under high fields as do piezoelectric and ferroelectric materials	Brittle ceramics that do exhibit dielectric breakdown

Equation 3.64), which is the force generated by a current-carrying conductor in a magnetic field. This magnetic force, in the case of a fluid, can be written out as follows:

$$F_L = \sigma \mathbf{EB} \tag{8.90}$$

where σ = conductivity of the fluid ($\Omega^{-1}m^{-1}$)
B = permanent magnetic field (Gauss)
E = electric field applied to the pump (V/m), which is E = V/L

Heng et al., using LIGA, microfabricated an MHD-type micropump. When operating in the DC mode, they observed significant bubble generation due to electrolysis of the fluid being pumped. The same group later worked on an AC-driven nozzle/diffuser type MHD to eliminate or reduce bubble formation.[140] In an AC MHD micropump, a sinusoidal AC electrical current and a perpendicular sinusoidal AC magnetic field pass through the electrolyte solution and transverse to a microchannel. The time-averaged

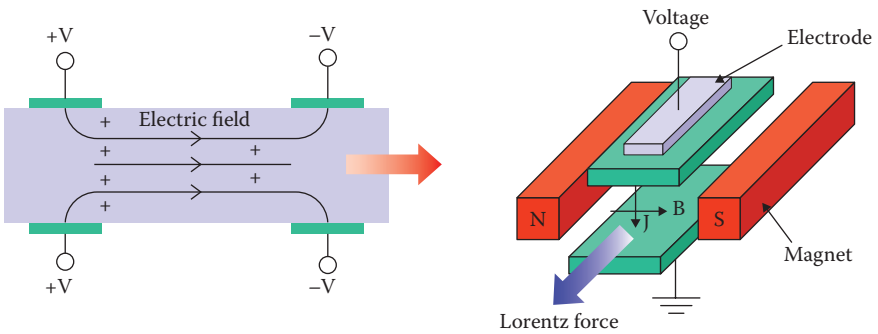

FIGURE 8.44 Schematic of a microelectromechanical system magnetohydrodynamic pump.

Lorentz force in this arrangement is given by the following equation:

$$F_L = IBw\int_0^{2\pi} \sin\omega t \sin(\omega t + \phi)d\omega t \qquad (8.91)$$

where I is the current amplitude and w the width of the microchannel. The ability to control the phase allows for controlling both the flow speed and the flow direction. Such an AC MHD micropump was demonstrated by Lemoff et al.[141] The same group also microfabricated an AC MHD fluidic switch in silicon with a switching speed faster than 0.033 s.[142] The switch is made by integrating two AC MHD pumps into different arms of a fluidic Y-channel. With a 1 M NaCl solution, a flow velocity of a 0.5 to 0.6 mm/s was registered in a 300-μm-deep, 1-mm-wide channel.

Magnetorheological Fluids, Ferrofluids, and Ferrowaxes

Magnetorheological Fluids

Magnetorheological (MR) fluids are colloidal dispersions of mesoscale size (1–10 μm) ferromagnetic particles suspended in polar or nonpolar carrier fluids. The particles are typically high-purity iron powders, but ceramic and alloys are used as well. These particles are multidomain and exhibit low levels of magnetic coercivity. As expected, the clumping of the suspended particles is caused by magnetic attraction.

When unperturbed by a magnetic field, MR fluids appear rather liquid. Upon applying a magnetic field, the viscosity of the fluid increases with the magnetic field magnitude in a nonlinear fashion. Upon reaching very high fields, the MR fluid becomes solid-like (Figure 8.45). As in the case of ER fluids, MR fluids

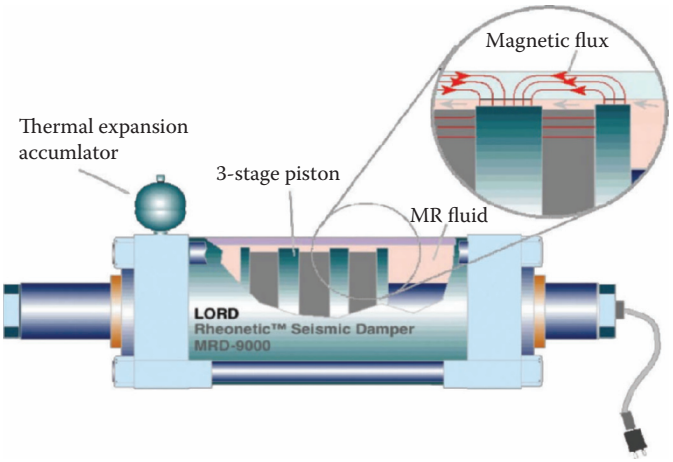

FIGURE 8.46 Magnetorheological fluid damper. Stroke: ±8 cm. Maximum input power: <50 watts. Maximum force (nominal): 200,000 N.

reverse to their original state upon removal of the external field. Overall response time of an MR system is of the order of milliseconds.[143]

MR fluids were discovered and patented in 1948 by Jacob Rabinow,[103] who was then with the National Bureau of Standards (NBS) [now the National Institute of Standards and Technology (NIST)]. After this invention, MR fluids basically disappeared from both the academic and industrial scene until the late 1980s. It is believed that the reason for this decline of interest in MR fluids in the early 1950s was that sedimentation and agglomeration of the magnetic particles were deemed unsolvable. This explains why knowledge of MR fluids is not as mature as that of ER fluids (see above), where the research remained more or less active after their initial discovery. Surprisingly, commercial success came first to MR fluids.

The main applications of MR fluids have been in the development of active vibration control and in the transfer of torque or force systems. In Figure 8.46, an MR fluid damper used in active building

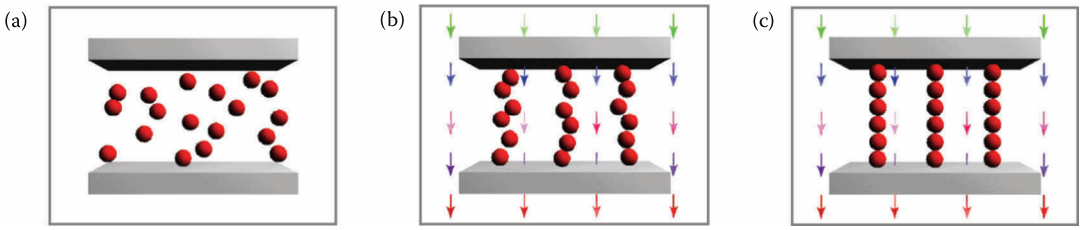

FIGURE 8.45 Magnetorheological fluids: (a) No magnetic field. (b) Intermediate magnetic field. (c) High magnetic field.

control (earthquakes) is shown. Another excellent application of MR fluids is the MagneRide by Delphi Corporation. A well-marketed magnetorheological suspension system, it was first used by GM in the Chevrolet Corvette C5, Cadillac Seville, and STS and is now also used in the Ferrari 599, the Audi TT, and the Audi R8. For more information, see http://delphi.com/manufacturers/auto/other/ride/magneride.

A major goal for the future in MR fluids is the more complete characterization of their performance depending on temperature, time, and shearing stress cycles. A hurdle in the path toward commercialization is the lack of suppliers of high-purity iron powder that makes the cost of MR fluid relatively high, even in large volumes.[143]

Ferrofluids

There are some notable efforts in nanoparticle-based MR fluids. Ferrofluids (FF) are a variant of MR fluids and are differentiated only by the size of the suspended particles used. In FF, one deals with particles smaller than 20 nm in diameter, whereas MR fluids are designed with particles in the micrometer size range (1–10 μm). The magnetic behavior of nanostructured materials has been investigated since the early days of nanotechnology. Some very significant results were first obtained by Herzer and Warlimont in 1992,[143] and an excellent review of the field by Herzer appeared in 1997.[144] When a ferromagnetic material is magnetized in one direction, it will not relax back to zero magnetization when the imposed magnetizing field is removed. It must be driven back to zero by a field in the opposite direction. If an alternating magnetic field is applied to such material, its magnetization will thus trace out a loop called a *hysteresis loop*. It is well known that the microstructure, especially grain size, determines the hysteresis loop of a ferromagnetic material.[144] It is found that the coercivity, H_c, the intensity of the magnetic field needed to reduce the magnetization of a ferromagnetic material to zero after it has reached saturation, increases with decreasing grain size down to values of about 40 nm for a pure metal such as iron or about 700 nm for hard magnets based on rare earth metals.[144] The reason for the H_c increasing proportional to $1/d$ is that as particles decrease in size, the magnetic domain size coincides more and more with the grain size. In this size range, multidomain (M-D) materials change to single-domain (S-D) materials. In the single-domain region, a change of magnetization can be produced only by rotation of the magnetization of a single grain or crystallite as a whole, which requires strong magnetic fields, depending on the shape and anisotropy of the particles. As the size of the magnetic particles is further scaled down, a transformation from ferromagnetic to superparamagnetic behavior occurs and the curve of H_c versus grain size d exhibits a peak at d_s (see Figure 8.47).[144] At particle size d_s, the material behaves as a purely single-domain material, and at d_p, the transition to a superparamagnetic is complete.

Typical particle sizes for the ferrro- to superparamagnetic (SP) phase transformation are between 10 and 20 nm for oxides and 1–3 nm for metals. This range corresponds to the band of lines drawn through the peak in the H_c-d curve. In the nanoparticle regime, between d_s and d_p, the coercivity exhibits a d^6 dependence.[144] In the superparamagnetic state of the material, the room temperature thermal energy, kT, where k is the Boltzmann constant, overcomes the magnetostatic energy of the particle (= domain), resulting in minimal hysteresis. In this case, even when the temperature is below the Curie or Neel temperature (and hence the thermal energy is not sufficient to overcome the coupling forces between neighboring atoms), the thermal energy is sufficient to change the direction of magnetization of the

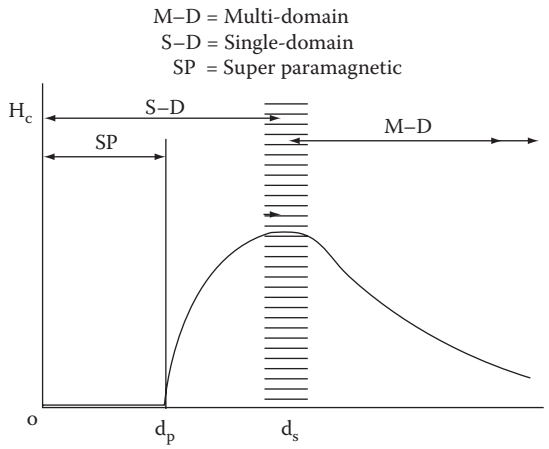

FIGURE 8.47 Coercivity (H_c) versus particle size. (Based on Herzer, G. 1997. In *Handbook of magnetic materials,* ed. K.H.J. Bushow, 417. Elsevier Science B.V.[144])

entire crystallite. The resulting fluctuations in the direction of magnetization cause the magnetic field to average to zero at d_p. Thus, the material behaves in a manner similar to paramagnetism, except that instead of each individual atom being independently influenced by an external magnetic field, the magnetic moment of the entire crystallite tends to align with the magnetic field. Superparamagnetic particles are attracted to a magnetic field but retain no residual magnetism after the field is removed (no hysteresis). These superparamagnetic nanoparticles feature a high-saturation magnetization, high relative permeability, low coercivity, high resistivity, and low hysteresis loss, and all of this benefits a large number of applications,* including in FF.

Superparamagnetic particles can be dispersed in a liquid, e.g., oil, without perceptible agglomeration if treated properly (see below and colloidal stability in Volume I, Chapter 7). Because of the nanometer sized particles in FF, sedimentation is prevented by Brownian motion, and agglomeration is avoided through the use of surfactants or ionic shells that coat the particles. If no coating is used, attractive van der Waals forces would cause the agglomeration of the particles. A typical FF constitutes a stable colloidal suspension of single-domain magnetic nanoparticles dispersed in a liquid carrier in a volume fraction of typically 2–10% (Figure 8.48). As explained above, MR fluids exhibit different viscosities depending on the strength of the magnetic field applied; FF, on the other hand, maintain their viscosity regardless of the magnitude of the magnetic field. Where MR fluids solidify in strong magnetic fields, FF always remain liquid.

In their natural state, with no field applied, FF are subjected to three forces: 1) repulsive forces due to the implemented coating, 2) attractive van der Waals forces, and 3) magnetic dipole-dipole interactions, which can be either repulsive or attractive. A true FF maintains equilibrium between the forces mentioned even in the presence of strong magnetic fields. A stable FF will not conglomerate for several years, until eventually the surfactants or the coatings on the particles break down and gradually cause the irreversible conglomeration of the particles into bigger clusters. At this point, the behavior of the FF tends to simulate that of an MR fluid.

FIGURE 8.48 Ferrofluid fixed with a magnetic field. The bottle is filled with ferrofluid and shows the magnetic force of the ferrofluid acting on the permanent magnet (Institute for Machine Tools and Factory Management, IWF, Germany).

Dispersed nanoparticles in FF are typically magnetite (Fe_3O_4) or maghemite (γ-Fe_2O_3), although cobalt, iron, and manganese zinc ferrite Zn_xMn_{1-x} have been used as well. The fluid carrier might be polar (water, in which case the FF are highly biocompatible) or nonpolar (hydrocarbons, fluorocarbons). Obtaining magnetic nanoparticles itself constitutes an important research field, and different methods have been attempted, with precipitation being the most common one (see Volume I, Chapter 7 and Chapter 3, this volume). Current applications of FF include positioning systems for multiaxle movement (see Figure 8.49), compliant positioning systems, dynamic sealing (e.g., on computer hard disks), bearings, adaptive gripping devices and dampers, and heat dissipation. Suspended superparamagnetic particles are also used to tag biomaterials of interest, the targeted species can be removed from a matrix using a magnetic field, but they do not agglomerate (i.e., they stay suspended).

Although perhaps not immediately or obviously useful, FF present a striking behavior when subjected to a normal magnetic field of strength above a critical value. Such fields induce a normal-field instability, causing the FF to instantly protrude from the surface in spikes aligned to the field lines, as

* On the other hand, it is also because of superparamagnetism that computer hard drive technologies are expected to stop growing once they reach a density of 150 gigabits per square inch.

Technical Data:

Load capacity: F < 10 N (in normal direction)
Accuracy of Positioning: ~ 1 μm

shown in Figure 8.50. The spikes are characteristic of equilibrium of gravitational force, magnetic force, and surface tension.

Many excellent videos have been created demonstrating this interesting behavior. A special mention goes to those obtained by Sachiko Kodama (http://www.kodama.hc.uec.ac.jp/protrudeflow/index.html), where art and technology are cleverly mixed to obtain beautiful FF patterns and behaviors.

Another interesting application along the same artistic lines is the creation of fractal droplets on a surface by confining a drop of FF between two glass slides in a Hele-Shaw cell* with a 0.9–1.4 mm gap (see Rinaldi and Zahn[145] and http://www.aps.org/units/dfd). When an FF drop is placed in such a cell and is subjected to simultaneous in-plane rotating and DC axial uniform magnetic fields and the magnitude of the fields increases, different, striking patterns are obtained (see Figure 8.51). The fluorocarbon-based FF used for the results shown here has a saturation magnetization of ≅400 Gauss and a low field magnetic susceptibility of $\chi \approx 3$. The FF is surrounded by a 50/50 mixture of isopropyl alcohol and deionized water that prevents the FF from wetting the glass plates. The rotational field strength is up to 100 Gauss rms at frequencies 20–40 Hz while the dc axial field is varied from 0 to ~250 Gauss.[146]

FIGURE 8.50. A normal-field instability caused by a magnet placed underneath the ferrofluid. (From Sachiko Kodama, http://www.kodama.hc.uec.ac.jp/protrudeflow/index.html.)

FIGURE 8.51 Fractals on a surface obtained by magnetic interaction of a field with a ferrofluid drop enclosed in a Hele-Shaw cell.[146] (From Prof. Markus Zahn, Massachusetts Institute of Technology.)

Next we detail an important microfluidic application of FF (i.e., valving and pumping) and highlight the prospect of ferrowaxes in fluidic platforms.

Hartshorne et al. demonstrated a FF-based valve.[147] In their work, a 600-cP FF was used to implement plugs to block fluidic channels. In air, this FF valve could hold pressures of up to 12 kPa (1.74 psi). When tested in water, water leakage at the FF/channel wall interface was observed. By making the channel walls hydrophobic, this water leak could be reduced. In the latter case, the valve could withstand pressures up to 10 kPa (1.45 psi). Besides their low pressure rating, FF plugs require the application of a magnetic

* A Hele-Shaw cell consists of two flat plates that are parallel to each other and are separated by a small distance, with at least one of the two plates being transparent.

field at all times in order to maintain the plug at the desired position.

An elegant approach for pumping with FF was introduced by Hatch and coworkers.[148] This team manipulated two FF plugs in a circular channel using a magnet that moves in a circular motion and maintains the plugs in place using stationary magnets. Using this scheme, one is able to pump defined volumes of liquid, given by the separation between the ferroplugs and the radius of the circular channel containing both pumping liquid and plugs.

Our team at University of California, Irvine, is attempting to use modified FF valves to create an inexpensive, normally closed, reusable valve that does not consume any power to stay closed. This type of valve is essential for all types of microfluidic platforms. For example, diagnostic reagents often must be stored on a chip or platform for months before they actually are used (the shelf-life of a diagnostics lab-on-a-chip device must be at least six months). Unless one has good, inexpensive liquid and vapor barriers/valves, liquids or vapors from the different reagent compartments will contaminate the system and even mix with each other, rendering the platform useless in a matter of hours. In principle, a regular pure wax valve fits the description: inexpensive, normally closed, and a good barrier for both liquids and vapors. Pal and colleagues[149] implemented pure wax valves, using paraffin wax and other waxes with higher melting points. Moving the resistance-heated molten wax by applying air pressure toggled the valve. Similarly, Liu and coworkers[150] used paraffin wax in their single-use valve. In this case, resistive heaters or Peltier elements melted the wax, while air pressure was again used for moving the molten wax. The authors claimed zero leakage when checking sealing against air. They measured a maximum holding pressure of 40 psi, while Pal et al. achieved 250 psi. Both groups succeeded in using a wax valve for sealing a polymerase chain reaction (PCR) chamber (remember that the maximum temperature needed for PCR thermocycling is ~92°C; see Figure 2.53). Liu et al. reported the use of paraffin valves (melting point ~50°C) 10 mm away from the PCR chamber, while Pal et al., using waxes with higher melting points (~85°C), could operate as close as ~5 mm from the PCR chamber. Use of microcrystalline waxes, with melting points up to 95°C, would be better yet for use in PCR applications.

An important drawback of the aforementioned wax valves is the need for an air pump to control the movement of the molten wax. This is where modified FF valves come in. A normally closed, reusable FF valve that provides effective sealing of a channel, for both vapors and liquids, and can be moved magnetically would thus be a very desirable feature. In the case of a regular FF valve, though, that objective is not met: to stay closed, a magnetic field needs to be applied, which is impractical during storage. Ferrowaxes, a modified type of FF valve, might be able to solve this problem.

In a ferrowax, magnetic nanoparticles are dispersed in a molten wax, and phase changes between solid and liquid are temperature controlled. A magnetic wax offers the opportunity of magnetic manipulation at will while the wax is molten and solidification at desired location (e.g., a valve seat) upon removal of the heat source. Additionally the wax, in its liquid phase, conforms to its holding container, and through the use of different kinds of waxes, the melting point can be tailored to different applications. Paraffin waxes appear to be the best choice for melting points of around 70–80°C, whereas microcrystalline waxes can take temperatures of around 95°C. Thanks to its nonpolar nature, the wax is immiscible in most biological samples. Advantages and disadvantages of the use of ferrowax are summarized in Table 8.15.

Kwang W. Oh and colleagues[151] demonstrated a ferrowax valve in a Y-shaped microfluidic junction. The valve is opened and closed by heating (using resistance heating) and magnetically displaced at will. The valve presented no leakage up to pressures of 50 psi.

Park and coworkers[152] implemented a single-use ferrowax valve in a compact disc (CD)-like centrifugal microfluidic device. This research group at Samsung took advantage of the absorption of laser energy by the embedded magnetic nanoparticles. The laser source operates at relatively low intensity to induce heat in the ferrowax causing a quick phase change to liquid. The pressure generated by the phase change causes the plug to move in a direction established a priori by the device's geometry, thus either

Table 8.15 Pros and Cons of Using Ferrowaxes

Pros	Cons
Relatively inexpensive	Heat source is required adding to the cost and complexity of the system
Energy efficient	Finite time of ferrowax phase change limits the time available for manipulation
Absorption of specific electromagnetic energy	Not yet commercially available (as of 2008)
Precision control	Industry scalability, since they require deposition of hot, viscous slurry
Nonpolar carrier used	
Melting point can be tailored	Melting point restricts the temperatures the at which the device might be used and/or stored
Do not interact with sample	
Conform to container geometry and provide an excellent seal after solidifying	

blocking or unblocking a channel or chamber. In this case, the magnetic nanoparticles are used solely to enhance heat absorption of the ferrowax and to induce a quicker phase change than that of paraffin wax alone. Our team at University of California, Irvine, tested the quality of the sealing of a ferrovalve for vapors and liquids qualitatively by immersing ferrowax sealed channels, containing calcium chloride, in a liquid environment. Even after more than twenty months, the calcium chloride did not show any sign of water uptake. A solidified ferrowax plug of around 2 mm in length with a cross-section of 1.75 mm^2 was also tested in a circular channel on the CD platform; the plug was located at a distance of 80 mm from the center of the rotating disc and did not show leakage up to 6000 rpm.

Regarding a real pumping application with ferrowax on the CD, the author's research group is currently exploring the use of these pumps to bring liquid samples back toward the center of the CD.[153] Indeed, a serious drawback in current CD microfluidics, besides the need of the type of valve described above, is the inability, after spinning fluids from the center to the rim, to move them back toward the center of the CD. This prevents the implementation of more complex diagnostic systems on a single standard-size CD, since the whole process of sample preparation and detection cannot be fitted easily onto a single CD platform. An FF plug could pump the sample back to the center of the CD for additional process steps (see also Volume I, Chapter 6, on fluidics, for more details on this CD platform).

The concept that we are implementing is the use of a ferrowax or FF plug as a pulling or pushing plug for the magnetic field to move the liquid inside a microchannel. To minimize water leakage at the interface of the pull/push plug and the CD plastic the walls of the channel are made hydrophobic. The concept is sketched in Figure 8.52. Theoretically, engineering a very soft ferrowax could eliminate the need for a heat source in a ferrowax system. In this case, the torque generated by the magnetic particles under a magnetic field could perhaps be made greater than the cohesion forces within the material, making the material move when a magnetic field is applied. The soft material might be a soft paraffin, gel-like polymer, or gelatinized nonpolar carrier that exhibits a "solid-like" behavior.

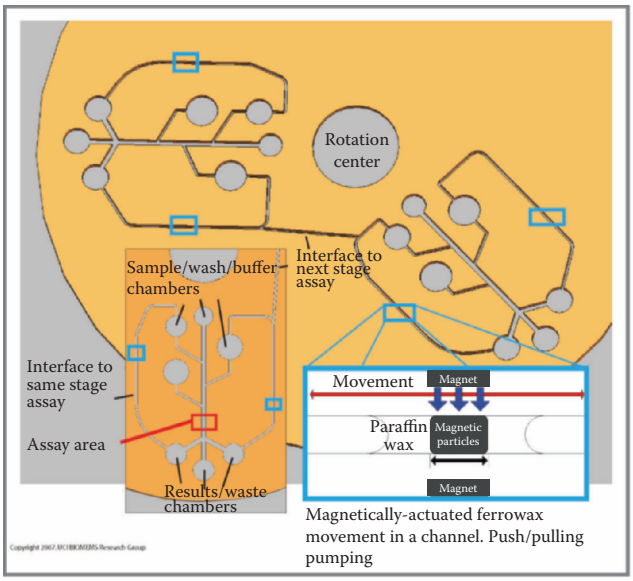

FIGURE 8.52 Schematic showing an example of a ferrowax pump. Ferrowax plugs, magnetically actuated by an external magnetic field, pull/push a sample toward the center of a compact disc (CD)-like centrifugal microfluidics platform. This way a sample might be reprocessed in one single CD platform, enabling a full diagnostic test (i.e., separation, filtration, amplification, and quantification) to be contained in a single platform. (From Zoval, J., and M.J. Madou. 2004. Centrifuge-based fluidic platforms. *Proc IEEE* 92(1):140–53.[153])

Superconductivity

Introduction

Given that actuators and power sources, in general, exhibit poor scaling in the microdomain, superconductors could play a dominant role in the more efficient powering and actuating of micromechanisms. The superconducting state is a new phase state in which, below a certain critical temperature (T_c), zero resistance and perfect diamagnetism is reached. It is well known that superconductors can levitate magnets because of their diamagnetism (Meissner effect). In this section we elaborate on superconductivity as it makes for the ideal Meissner levitators.

The levitating permanent magnets described above are ferromagnets with a positive and very large magnetic susceptibility, χ_m (χ_m usually is only constant in a small range of magnetization). Levitation can also be based on diamagnetic materials for which χ_m is small and negative. In diamagnetism, as a magnet approaches a diamagnetic material, magnetic dipole moments are induced in the diamagnetic material that oppose the applied field. These dipole moments lead to magnetic forces that tend to push away the magnet. Some ordinary diamagnetic materials, such as carbon and bismuth, with a χ_m of about -1×10^{-6} (compared with -0.20×10^{-6} for Au or -0.11×10^{-6} for Cu), can levitate magnets at room temperature. Although only a small force per unit mass, this kind of levitation does not require power, operates at room temperature, and can be used with a variety of materials. Kim et al., for example, levitated a permanent-magnet mover by applying the Meissner effect.[110] The ideal would of course be to have superconductivity at room temperature, but even a material superconducting at liquid nitrogen temperature (77 K) is amazing [liquid nitrogen ($1.04/L) is much cheaper than liquid helium ($3.75/L) and far easier to handle].

The Discoveries

Superconductivity represents a macroscopic quantum effect: one of the few cases where quantum effects become observable on a macroscopic scale. The electrons in a superconductor behave as a single particle. The Dutch physicist, Heike Kammerlingh-Onnes (1853–1926) (Figure 8.53), discovered the phenomenon in mercury in 1911, and in 1913, he received a Nobel Prize for his work.* The superconducting state may be defined as a new phase state in which, below a certain critical temperature (T_c), zero resistance and perfect diamagnetism is reached.

Heike Kamerlingh Onnes
(1853-1926)

FIGURE 8.53 The Dutch physicist Heike Kammerlingh-Onnes (1853–1926).

Most high-purity metals, when cooled to temperatures nearing 0 K, exhibit a gradually decreasing electrical resistivity, approaching some small yet finite value characteristic of the particular metal. For a few superconducting materials, such as mercury and indium, resistivity abruptly plunges from a finite value to one that is virtually zero at very low temperatures and remains there upon further cooling. Loss of resistance to electrical current flow occurs below a critical temperature, T_c. Below that temperature superconductors offer an energy transfer medium with virtually no power loss. In the case of pure elements such as mercury (see Figure 8.54) and indium, the T_c is between a few and 10 K. The change from the normal state to the superconducting state occurs over a temperature range of about a thousandth of a degree. One might wonder then if the resistance, R, really is zero and how one measures a zero resistance. To measure R = 0, a loop of a superconductor is made, a current is injected in it, and the magnetic field due to this current is measured as a function of time. Carrying out these experiments

* Kammerlingh-Onnes was also the first to liquefy helium at 4.2 K, using a "fancy" refrigerator, in 1908.

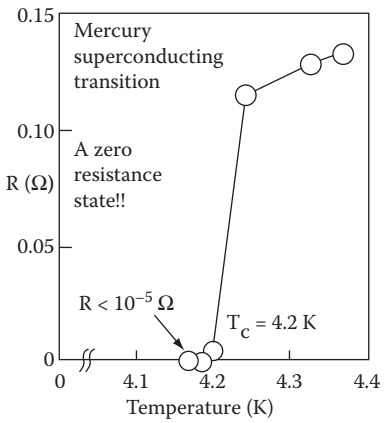

FIGURE 8.54 Mercury becomes a superconductor below 4.2 K.

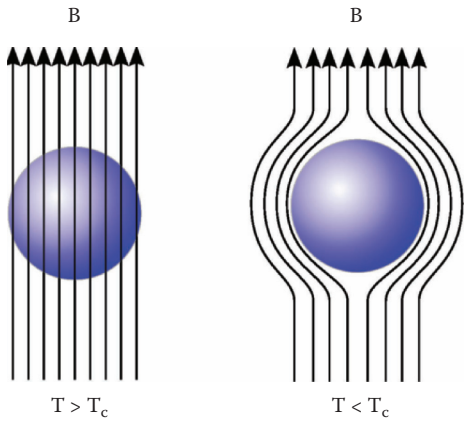

FIGURE 8.55 The Meissner effect for type I superconductors at $T > T_c$ and $T < T_c$.

turns out to be very boring, after monitoring the current via the magnetic field it generates for a number of *years* and observing no change, scientists typically shut the experiment down. We cannot say from this experiment that the resistance is really zero, but we can at least say it is far smaller than any capability or patience of ours to measure (the theory says it really is zero). In other words, once set in motion, electrical current will flow forever in a closed loop of a superconductor (R = 0), and all magnetic fields will be expelled from the same chunk of material (perfect diamagnetism). The Holy Grail for superconductivity researchers is, of course, a room-temperature superconductor, which would exhibit perpetual motion. But even a material superconducting at liquid nitrogen temperature (77 K) is amazing. [Liquid nitrogen ($1.04/L) is much cheaper than liquid helium ($3.75/L) and far easier to handle.]

The curious magnetic property of superconductors in which the material expels all traces of magnetism from its interior is called the *Meissner effect*; it was discovered in Berlin, in 1933, by Walther Meissner and Robert Ochsenfeld. Superconductivity baffled classical physicists. Below T_c there can be no resistance, so there can be no voltage inside the superconductor, and from Faraday's law it follows that the magnetic field inside cannot change. However, we actually observe that the field lines from the external field are "expelled" from the superconductor. How is that possible? The explanation is that a supercurrent (screening current) is induced on the surface in a direction such that it cancels the external field (see Figure 8.55). The magnetic field generated is strong enough to overcome gravity, so that a magnet can be made to levitate over the superconductor (see below, Figure 8.60). A superconductor such as this, which exhibits a complete Meissner effect, is called a *type I superconductor*, a soft superconductor, or a low-critical-temperature superconductor (LTS). Such a superconductor is limited in its current-carrying capability because it can tolerate only very small magnetic fields. As we shall see below, type II semiconductors can carry much larger currents but are not perfectly diamagnetic.

Among pure elements, niobium shows the highest temperature for superconductivity, and there are about a dozen niobium compounds (examples include niobium carbide, niobium titanium, niobium gallium, and niobium germanium) that all show super conductivity up to about 30 K (liquid hydrogen range). Nb_3Ge was discovered in 1973 and was long the record-holder for highest T_c (see Figure 8.56). Some of the niobium compounds have been drawn into wires to produce very compact magnetic fields for use in, for example, magnetic resonance imaging (MRI). In Table 8.16 we present a review of typical metal superconductors.

Until 1986, the T_c was 23 K for the best low-temperature superconductors, requiring liquid helium for maintaining the superconductivity state. In 1986, Bednorz and Muller (Figure 8.57), working at the IBM Zurich Research Laboratory, discovered higher-temperature (35 K) superconductivity in a lanthanium-barium-copper oxide. Their compound was a ceramic material and, ironically, a very poor conductor at room temperature.

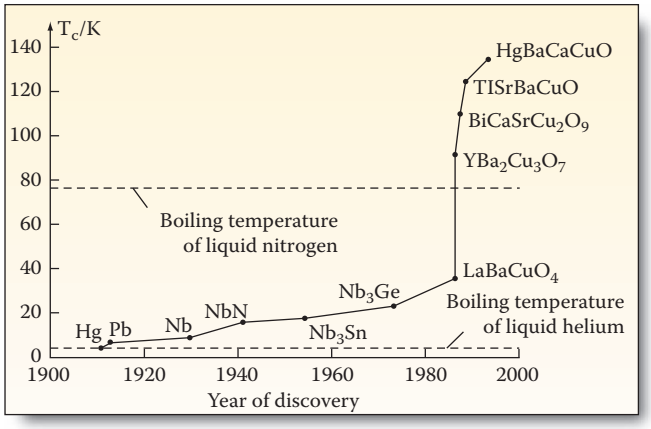

FIGURE 8.56 The critical temperature, T_c, of various superconductors plotted against their discovery dates.

FIGURE 8.57 George Bednorz and Alex Muller, 1987 Noble Prize winners.

Bednorz and Muller's ceramic was the first nonmetal that begins to superconduct above the boiling point of liquid hydrogen. Their invention triggered a race to find superconducting materials with transition temperatures above 77 K, the boiling point of liquid nitrogen. Overnight, anybody who knew about superconductors or ceramics started cooking up new compounds in his or her furnace, and a record number of high-temperature superconductors was announced over the next couple of years (see Figure 8.56). Paul Chu, of the University of Houston, made a stunning breakthrough when he announced the discovery of a material that became superconducting at 93 K, well above liquid nitrogen temperature. Early in 1987, Chu circulated a preprint of a paper describing superconductivity at 93 K in a ceramic containing Yb, Ba, Cu, and O. When the paper appeared in print, every Yb (ytterbium) had been replaced by Y (yttrium)! It was just a typo, Chu* explained. By January 1988, another copper-oxide material was shown to exhibit superconductivity at a high temperature, 110 K. The world record T_c for a superconductor is 138 K, for a compound containing mercury, thallium, barium, calcium, copper, and oxygen. Some superconductor ceramic materials are listed in Table 8.17. The new breed of ceramic superconductors is referred to as *hard superconductors*, *type II superconductors*, or *high-critical-temperature superconductors* (HTS). The two types of superconductors are compared in Figure 8.58.

In the case of a small applied magnetic field, type II superconductors act like type I superconductors. In the presence of large magnetic fields, a type II "sacrifices" part of itself so that the rest can remain superconducting. These superconductors contain vortices that are filaments of the material in the normal

* This would not be the last intrigue haunting superconductor research. In May 2002, outside researchers presented evidence to Bell Labs management of possible manipulation of data involving five separate papers published by its scientists in *Science, Nature,* and *Applied Physics Letters* over a two-year period by Jan Hendrik Schön as lead author and his colleagues at Murray Hill and elsewhere as coauthors. Schön is the only researcher who coauthored all five papers in question.

TABLE 8.17 Examples of Type II Superconductors with Their Critical Temperatures (T_c)

state as shown in Figure 8.59. The magnetic field lines pass through those vortices. High-temperature superconductors thus exhibit only a partial Meissner effect. Compared with type I superconductors, type II superconductors can carry enormous currents (in some cases, superconducting wires can carry currents that are thousands of times larger than those that can be handled by ordinary wires of similar dimensions), but these brittle ceramics are very difficult to fabricate into wires.

In Figure 8.60, we show a magnetic cube, placed on a disc made of a superconductor material. As the disc is cooled down with liquid nitrogen, superconductivity sets in below its critical temperature and the magnetic repulsion levitates the cube.

The Model of John Bardeen, Leon Cooper, and Robert Schrieffer (BCS Model)

The mechanism of superconductivity remained a mystery from 1911 until 1957. The abrupt change from normal state to superconductive state indicated

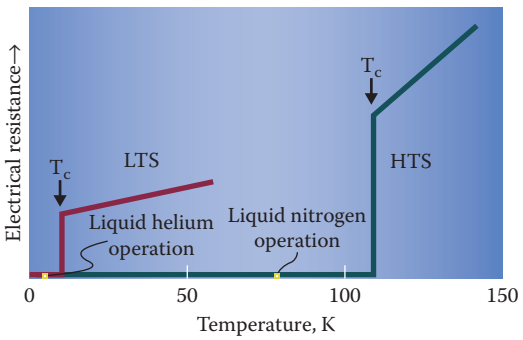

FIGURE 8.58 Low- and high-critical-temperature (T_c) superconductors compared.

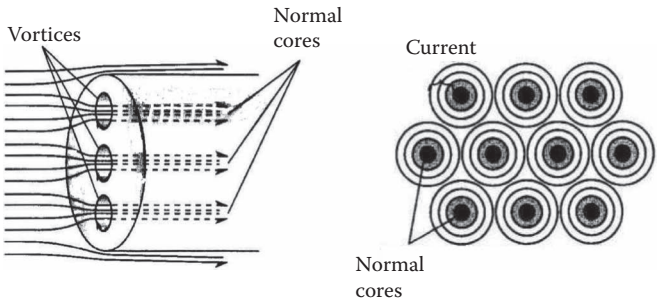

FIGURE 8.59 Type II superconductors expel magnetic fields just as type I superconductors do but contain vortices of the metal in the normal state. This is called a *partial Meissner effect*.

clearly that superconductivity is not merely an extension of ordinary conductivity. Three important observations having to do with superconductors that gave hints about its origins were the following:

1. The Meissner effect exists.
2. The "best" metals do not seem to be superconductors. Among superconducting metals, better metals make poorer superconductors, and vice versa.
3. A lighter isotope of mercury becomes superconducting at a higher temperature (i.e., more readily) than a heavier isotope.

From quantum theory, we know that electrical conductivity arises because of acceleration of electrons near the Fermi surface and that electrons move in conductor-like waves rather than as particles. Because they act as waves, electrons may travel

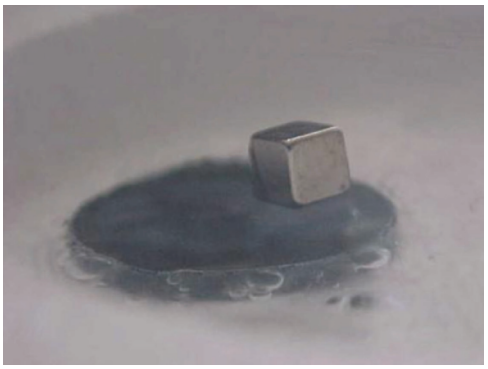

FIGURE 8.60 A magnetic cube is placed on a disc made of a superconductor material. As the disc is cooled down with liquid nitrogen, superconductivity sets in below its critical temperature, and the magnetic repulsion levitates the cube.

FIGURE 8.61 The theory of superconductivity by Bardeen, Cooper, and Schrieffer (left to right) earned them a joint Nobel Prize in 1972.

through a metal without colliding with the metal ions, and consequently, in principle at least, one could get zero resistance. If electrons do not collide with metal ions, what do they collide with? After all, metals do have finite resistivities? As we discovered in Volume I, Chapter 3, even in a pure material, thermal oscillations of the atoms, or phonons, will scatter moving electrons, causing finite resistivity; electrons do not bump into ions at the regular crystal sites but scatter from ions that happen to be vibrating and in the "wrong" place when the electron wave passes by. Impurity atoms and defects such as vacancies, dislocations, and twin and grain boundaries will scatter the electrons even more, further increasing the resistivity. When the temperature is lowered, the phonon contribution to resistivity is expected to fall away, but the contribution caused by impurities should remain finite. In the case of superconductivity, all these resistance-causing factors are somehow overcome.

John Bardeen, Leon Cooper, and Robert Schrieffer (Figure 8.61), all at the University of Illinois, first explained superconductivity in 1957 and won the 1971 Nobel Prize for their BCS model (this was Bardeen's second Nobel Prize). The model works for low-temperature superconductivity only; there is no explanation yet for the ceramic HTS. The key observation that led to the BCS model was the isotope effect, which puts one on the trail of phonons; since isotopes are involved, atoms, and perhaps their movement, must somehow play a role in the phenomenon. To start the argument, remember that in a normal metal conductivity (σ) is proportional to scattering time (τ). In superconductors, there are no final states for the scattered electrons to go to, so scattering is simply quantum mechanically not allowed. What this means is that the difference between a normal metal and a superconductor is that in the case of the superconductor there is a bandgap, as shown in Figure 8.62.

Because of this bandgap in momentum space, scattering is forbidden, i.e., there are no final states for scattered electrons to go to. The energy gap is caused by attractive interaction between electrons. Somehow pairing of electrons reduces their energy. This is rather curious; how can electrons attract each other and form pairs with a lower energy content? The answer is that there is a *phonon glue* that causes their interaction to be attractive.

This needs some further detailing. Phonons, as we know, are periodic vibrations of atoms in solids; think of plucking an atom with nanotweezers. The forces between the different atoms pull the plucked

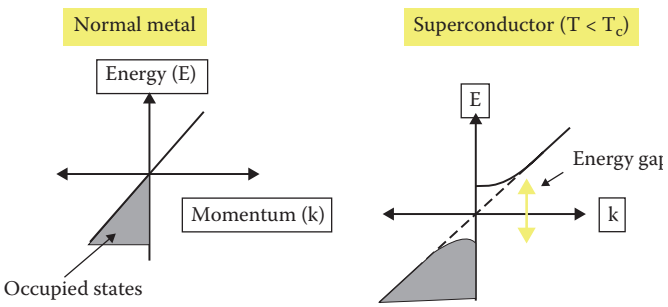

FIGURE 8.62 An energy bandgap in momentum space in a superconductor.

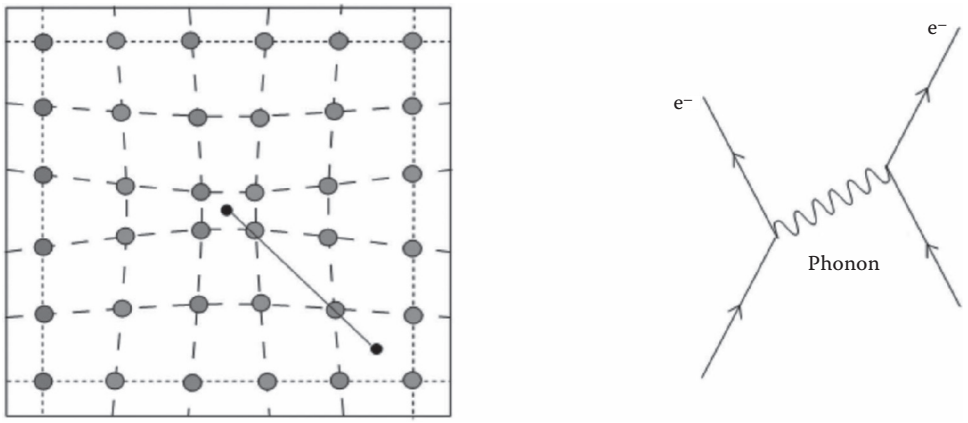

FIGURE 8.63 Pairing is mediated by crystal vibrations (phonons), and a distortion of the lattice as shown causes Cooper pair formation.

atom back into position, setting up a wave of atomic vibrations that travels through the material. Pairing is mediated by these crystal vibrations (phonons), and it is a distortion of the lattice, as shown in Figure 8.63, that allows the formation of the Cooper pairs, as shown in Figure 8.64, to take place.

A close-up of the crystal deformations leading to the formation of Cooper pairs is shown in Figure 8.65. As electrons travel between the ion cores of the metal they exert an attractive force on the positive nuclei, and these move very slightly away from their idealized positions. As a result of this disturbance, the distribution of positive charges is no longer uniform and features regions of small excess of positive charges. This extra charge is sufficient to attract a second electron, and so two electrons are linked, albeit indirectly. If the attraction exceeds the electron-electron repulsion, a "bound pair" is formed. The bound pair is called a *Cooper pair*. This mechanism explains why good conductors such as Cu and Ag are poor superconductors; these materials are good conductors at room temperature exactly because their conduction electrons do not strongly interact with the ion cores, and as a consequence we would not expect such materials to form good superconductors since the mechanism for forming pairs is very weak. This pair formation also explains the abrupt change from normal to superconducting state. Such a sudden transition is known as a *phase change*. Just as ice melts suddenly at 0°C, the thermal motion of the molecules at a critical temperature abruptly destroys the Cooper pairs.

The model also explains why a lighter isotope of mercury becomes superconducting at a higher temperature (i.e., more readily) than a heavier isotope; the smaller the mass of the positive ion core, the greater the distortion an electron can induce (to be more exact, $T_c M^{1/2}$ = constant). But how do those Cooper pairs explain superconductivity? Electrons in a superconductor move in correlated pairs in such a way that the properties of each pair are the same

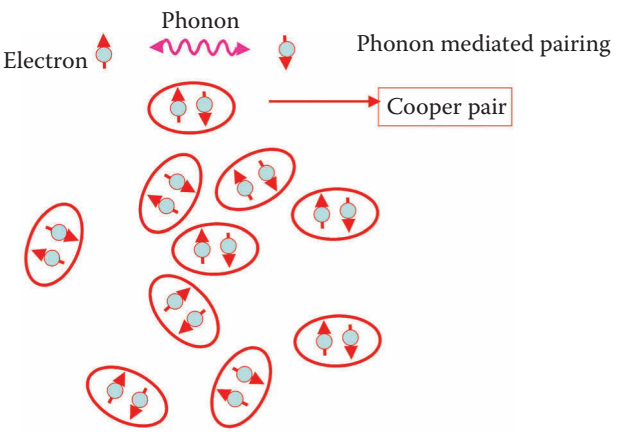

FIGURE 8.64 Cooper pair formation.

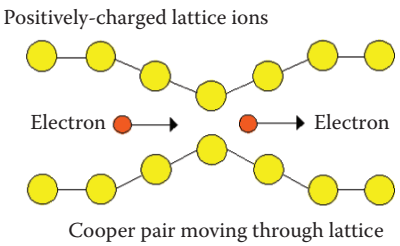

FIGURE 8.65 A lattice deformation forming a Cooper pair.

as those of all the others. These paired electrons are not necessarily close; on average they might be separated by hundreds or even thousands of atom spacings. The maximum distance up to which the states of paired electrons are correlated to produce superconductivity is called the *coherence length*. Coherence length of Cooper pairs is about 10^{-4} cm.

The electrons in Cooper pairs have opposite spins and equal and opposite linear momenta, or the pairs have zero spin and zero momentum, which makes them bosons instead of fermions (see Figure 8.66 and Volume I, Chapter 3).

In the absence of a current there is no net movement of electrons, and all the electron pairs have an average velocity of zero. Zero-spin particles such as Cooper pairs are bosons (like photons and phonons), and they "like" each other so much that they all crowd together in the same state (energy and momentum). Cooper pairs condense into one macroscopic quantum state with ~10^{23} particles that are all coherent. If a current flows, all the pairs have the same velocity and move in the same direction, as one collective body. In the superconducting state, the Cooper pairs are constantly scattering each other, but the total momentum remains constant. Remember—the paired electrons have opposite momentum. If one gains momentum, the other loses momentum. Because all Cooper pairs act together, a single lattice ion cannot scatter a single Cooper pair or they do not lose energy by interacting with the lattice. With all the electrons acting as a team, the only resistance possible is for all electron pairs to simultaneously scatter into a different state, an event that is so implausible that all attempts to measure any resistance in a superconductor have failed. This is the same as saying that there are no energy levels for the scattered pairs to go to, or that there is an energy gap. Because all the electrons act together to form a single quantum state, electrons flow around a wire as electrons in an atom do. Zeeman splitting takes place when a material is placed in a high magnetic field. When Zeeman splitting occurs in superconductors, the field is great enough to force a Cooper pair to occupy the same energy level and thus spin in the same direction. This breaks the Cooper pairs and superconductivity.

In summary, the BCS model is based on a phonon-mediated attractive interaction between electrons, leading to the formation of Cooper pairs; these pairs act like bosons, which fall into a coherent superconducting state. BCS theory beautifully explained all aspects of superconductors, but it seemed to predict that 30 K (give or take a couple of degrees) is the highest possible temperature at which a material could be superconducting, as above that temperature lattice vibrations destroy the Cooper pairing: the BCS model explains the LTS but not the HTS. BCS theory is clearly a good starting point, and just as clearly it is not the final answer. If we understood HTS, it might be possible to propose a room-temperature superconductor.

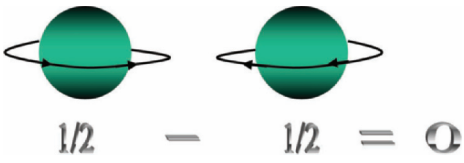

FIGURE 8.66 How to make bosons out of electrons.

Thermal Actuators[68]

Introduction

In thermomechanical actuators (TMAs), thermal energy is transformed into mechanical movement. A μ-TMA generates controlled motions via thermal strains. The simplicity of the system is the major reason that many MEMS devices are actuated by thermal means.

In Figure 8.67, we illustrate an example of a TMA, i.e., a parallel beam μ-TMA. By applying a current, the narrow beam shown in this structure is heated

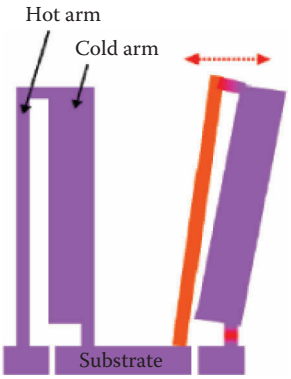

FIGURE 8.67 Parallel beam thermomechanical actuator.

up more and expands also more because of its higher resistance and higher current density than the wider beam, causing a movement as indicated. Removing the current restores the structure to its original position.

Scaling of Thermal Actuators

Scaling laws in heating and cooling, such as the total amount of heat required to start a thermal actuator, its heating and cooling rate, the thermal stresses or distortions expected, and possible damage to delicate MEMS and NEMS components, were detailed in Volume I, Chapter 6. In the same chapter we also analyzed the breakdown of the heat transfer continuum theory in the microdomain, and in Volume I, Chapter 3, we discussed quantized thermal transport in nanoscale devices.

Here we reiterate the most salient points of those scaling insights as they apply to thermal actuators:

1. Small devices, having a smaller mass, heat and cool faster than larger structures (see Volume I, Equation 6.68).
2. The Biot number (Bi) relates the heat transfer resistance inside and at the surface of a body (Volume I, Equation 6.70). This dimensionless number gives an indication of the potential for thermal stresses. For Bi $\ll$ 1, internal temperature gradients become small and the microstructure can be treated as having a uniform temperature. In the microscale, the Bi is small, so that conduction accounts for 99% of the energy transport. Consequently, with small devices there is less worry about thermal stresses induced by thermal gradients, and systems with larger internal heat generation capacity by volume can be built.
3. The increased phonon-boundary scattering in nanostructures lowers the thermal conductivity κ (see Volume I, Chapter 3 and Chapter 3, this volume). This contributes, for example, to making better heat insulators and more efficient thermoelectrics.

From the above, the micro- and nanodomain seems especially appealing for thermal actuator applications.

Types of Thermomechanical Actuators

Introduction

In this section we compare pneumatic, bimetallic, and shape memory alloy thermal actuators by considering their use in microvalves. These three types of thermal actuator mechanisms employed in microvalves are illustrated in Figure 8.68. In the section that follows we detail the choice of actuator types in commercially available valves.

Thermopneumatic Actuators

The thermopneumatic valve (see Figure 8.68a) traps a liquid in a sealed cavity containing a thin film heating resistor along one side of the cavity, with a flexible diaphragm wall forming the opposite side.[154] Upon heating, the fluid in the chamber expands and evaporates, raising the pressure in the sealed cavity and causing the flexible wall to bulge outward. In a normally open valve, this bulging diaphragm closes a nearby orifice. In a closed valve, as illustrated in Figure 8.68a, actuation levers a silicon body away from an orifice. Compared with other microvalve technologies, thermopneumatic actuation exerts tremendous force through a long stroke. In a normally open valve, over 20 N through a stroke of 50 μm was demonstrated.[154] This long stroke allows a thermopneumatically actuated valve to control higher flow rates and a wider range of pressures. This type of valve was made at Redwood Microsystems, Inc., a company that is now defunct.

Bimetallic Actuators

The second thermal actuator, illustrated in Figure 8.68b, is a bimetal. A bimetal involves the combination of two materials with distinct thermal expansion coefficients. A bimetal strip will bend when heated or cooled from the initial reference temperature because of incompatible thermal expansions of the materials that are bonded together. The bimetal returns to its initial reference shape once the applied heat is removed.

In the case of a bimetal structure based valve, as illustrated in Figure 8.68b, the nickel and silicon relax and the valve is closed when cold; upon heating, the nickel expands more than the silicon, lifting

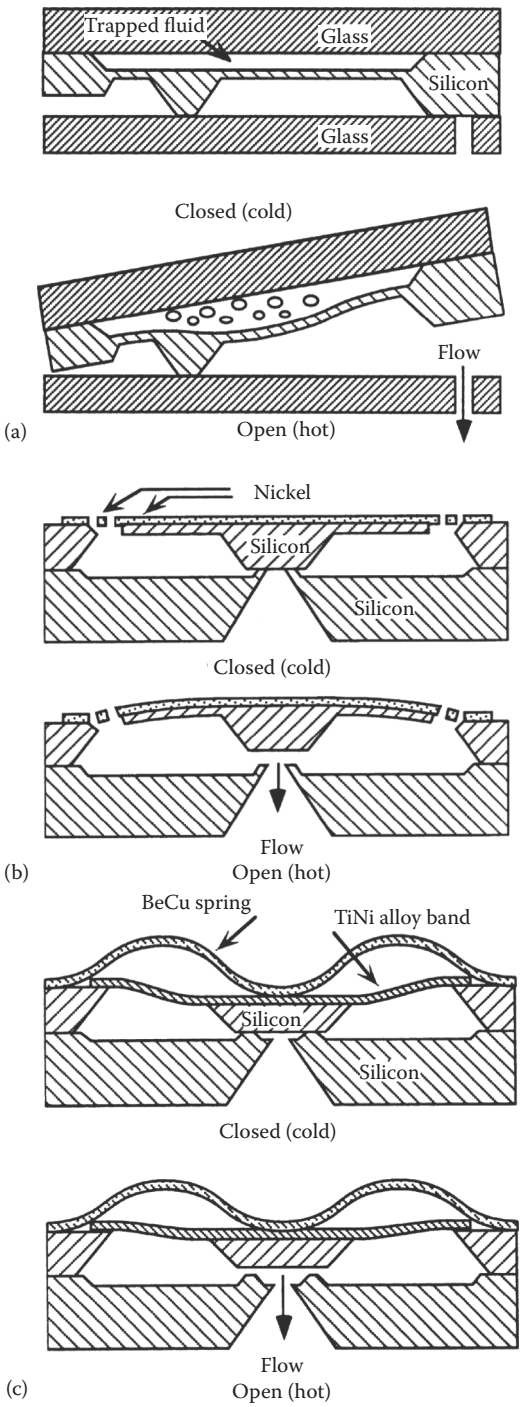

FIGURE 8.68 Schematics of thermally actuated valves. (a) Schematic of a normally closed thermopneumatic valve. (After Zdeblick, M.J., R. Anderson, J. Jankowski, B. Kline-Schoder, L. Christel, R. Miles, and W. Weber. 1994. In *Technical Digest: 1994 Solid State Sensor and Actuator Workshop,* 251. Hilton Head Island, SC.[154]) (b) Schematic of a normally closed nickel/silicon bimetal valve. Stockholm, Sweden.]

the silicon body from the valve seat. In terms of size, bimetal actuators are smaller than thermopneumatic ones and consume less power, but they lack the longer stroke of the latter.[155]

Shape Memory Alloy (SMA) Actuators

A third thermal actuator is based on shape memory alloys (see Figure 8.68c). Shape memory alloys undergo reversible thermal-mechanical transformations of their atomic structure at certain temperatures. Specifically, SMAs such as NiTi undergo crystalline phase transformations from a weak and easily deformable state at low temperatures to a hard and difficult-to-deform state at higher temperatures. The material is first held in the desired shape and heated to well above the transition temperature (T_{tr}). At these temperatures, the crystal structure is in the austenite or parent phase. Cooling transforms the material into martensite, the low-temperature phase, which plastically deforms (solder-like) by as much as 10% at relatively low stresses (yield strength is only 100 Mpa). When the SMA is heated again above its transition temperature, T_{tr}, it transforms back to the high-temperature phase (austenite) and reverses to its originally high-temperature shape, exerting a substantial force (>100 MN/m^2). The austenite phase has a much higher yield point and can sustain stresses up to 560 MPa without permanent deformation.[156] The large forces make SMAs ideal for actuation purposes; piezoelectric and electrostatic actuators exert only a fraction of the SMA force, but they act much faster. The temperature interval over which the shape change takes place typically is 10–20°C. The lowest energy path to the austenite exactly retraces the atomic movements responsible for the deformation, causing the shape memory. The discovery of the effect in 1951 involved a gold-cadmium alloy, but this was soon extended to a broad range of other alloys, including titanium-nickel, copper-aluminum-nickel, iron-nickel, and iron-platinum alloys. For practical applications, Ni-Ti, Cu-Zn-Al, and Cu-Al-Ni all have been tried. Depending on the type of alloy and the alloy composition, critical temperatures range between –150°C and +150°C.

Besides their use in μ-valves, shape memory alloys have been used in numerous applications (see Figure 8.69) including medical (e.g., microsurgical

(a) (b)

FIGURE 8.69 Examples of shape memory alloy (SMA) applications. SMA valve opens and releases hot water at the proper temperature (a). NiTi surgical tools: precise bending of the tool to the proper shape in microsurgery (b).

instruments, stents, artificial muscle), aerospace (e.g., connectors, lock rings), automotive (e.g., Ni-Ti thermostat), industrial (e.g., pipe connectors), consumer (e.g., eyeglass frames), and safety (e.g., fire safety valves).

The most extensive work with shape memory alloys involves bulk materials and bulk titanium-nickel alloys in the form of wires and rods, which are commercially available under the name Nitinol™. Nitinol, a composition transforming near room temperature, is traditionally prepared with 50% Ti and 50% Ni. Increasing the Ni content decreases the transition temperature by about 25°C per 0.2 at % Ni. The material is a good electrical conductor, with a resistivity of 80 μΩ·cm, but a relatively poor thermal conductor, with a thermal conductivity about one-tenth that of silicon.

The more IC-compatible sputtered films were made in the late 1980s by Walker et al.[157] at Bell Labs and by Busch and Johnson[156] at TiNi Alloy Company (http://www.sma-mems.com). Thin-film, nickel-titanium shape memory alloys up to 50 μm in thickness have been sputter deposited. These films exhibit memory behavior comparable to bulk material, and the phase transition to and from martensite lies entirely above ambient temperature (see Figure 8.70).[158] When deposited at room temperature, NiTi films are amorphous. Heating to 500°C causes the film to crystallize and acquire its shape memory property.[158]

Some materials and processes are incompatible with such high temperatures, requiring either rapid thermal annealing (RTA) or a special choice of materials and careful selection of the order in which processes are carried out. Another limitation of thin-film NiTi is the upper limit of 70–80°C for transition temperature T_{tr}, which is too low for applications such as valves for fuel injection systems and many military applications. Experimentation with higher-temperature tertiary alloys such as TiNiHf is under way to alleviate this problem. The bandwidth of the NiTi films is slightly improved, to about 5 Hz, compared with the NiTi wire (about 1 Hz) because of the more effective cooling in the microdomain. Another advantage of TiNi thin-film actuators is that they are biocompatible and transistor-transistor logic (TTL) voltage compatible.

We compared the energy density and drive conditions for NiTi with magnetic, electrostatic, and piezoactuators in Table 8.8. NiTi outperforms magnetic and electrostatic actuation in terms of energy density and may cause large motions in the range from 10 μm to 1 mm, operational requirements not well matched by electrostatic or piezoelectric

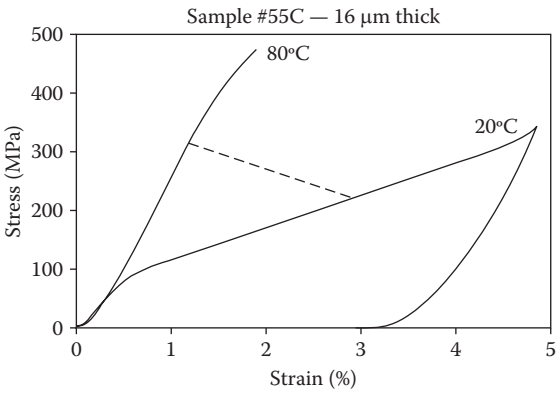

FIGURE 8.70 Stress-strain curve for a TiNi shape memory alloy thin film. The sloping, broken line indicates a load line spring force resisting the actuator, showing a 2% repeatable strain recovery. (After Johnson, A.D. 1991. Vacuum-deposited TiNi shape memory film: Characterization and applications in microdevices. *J Micromech Microeng* 1:34.[158])

technologies. As the required voltage for actuation is low (a couple of volts), it becomes compatible with IC technology. The phase change in SMAs is temperature driven, and as heat must be removed before the next cycle starts, this makes the system inefficient—the cycle rate may be slowed down by the achievable rate of heat transfer. The ultimate efficiency cannot exceed that of the Carnot cycle operating between the same temperature limits.[159] Practical SMA actuators have an efficiency typically less than 10%; for example, 50 J of heat input might be required to obtain 1 J of mechanical energy output.[158] However, in very small devices, heat transfer is rapid, which makes this type of actuator more attractive. Another potential disadvantage is the need, in most applications, of mechanical biasing devices to provide a return force such as the BeCu spring, enabling cyclical behavior in the normally closed valve sketched in Figure 8.68c. The beryllium-copper spring puts bands of SMA in tension over the orifice at low temperature. The SMA bands constitute electrical resistors and are heated by current passage. At high temperature, the SMA element works against the BeCu spring to reach its high-temperature preset form and moves away from the valve seat, opening the valve. At low temperatures, the spring easily pushes the silicon body back onto the valve seat, closing the valve. The spring adds somewhat to the size of the SMA actuator and also further slows down the response time (0.5–2 Hz). If the high-temperature shape does not change upon cooling the specimen and transforming it to the martensic phase, the phenomenon is referred to as a *one-way* shape memory effect, and springs or other mechanical biasing mechanisms are required. Solutions to avoid mechanical biasing might be within reach: SMAs can, under certain circumstances, remember their low-temperature shape as well, enabling cyclic device operation without the need of a bias.[160] In the latter case, one refers to a "reversible" shape memory effect. The low bandwidth of SMA usually is assumed to be determined by the relatively long cooling thermal time constant. Hunter et al. report an interesting unexplained effect in which very large brief current pulses (>10^9 A/m^2), imposed during externally shortening and lengthening cycles, alter the subsequent NiTi switching properties.[161] The altered NiTi shortens and lengthens very rapidly (within 40 ms) and generates a maximum extrapolated stress of 230 MN/m^2 and a peak power/mass approaching 50 kW/kg.[161]

Shape memory plastics also are being developed. Norsorex, for example, is the trade name for a polynorbornene polymer with excellent shape recovery properties at shape memory temperatures of over 35°C. Another polymer is Zeon Shable, a polyester-based polymer blend.[162] There are many potential applications for shape memory alloys and patents abound in this area (upwards of 15,000).

Summarizing, the advantages of SMA actuation include high force/weight and force/volume ratios, large deformation, simplicity of implementation via a heating current fed through the SMA material, simple cooling by the ambient environment (especially effective for small structures with a small Biot number), and inexpensive raw materials. Disadvantages include the one-way operation necessitating a bias force, heating/cooling cycles that reduce the bandwidth, the number of cycles reducing the maximal deformation (after >10^5 cycles, the maximal deformation is less than 4%), the fact that cycling changes the properties of the alloy, hysteresis (10 … 30°C), and nonlinearity.

Comparison of Actuator Principles in Commercial Valves

Miniature, highly accurate valves are of importance in many industrial operation processes. In Table 8.18, listing four commercially available thermal valve technologies, we compare the merits of the various underlying thermal actuator mechanism reviewed in this section.[155] Parameters of interest for valve performance include power consumption, actuation speed, force, stroke, cost, and package size.

Hewlett-Packard (HP) has come up with a thermally actuated valve intended for a very small, possibly handheld, gas chromatography (GC) system.[163,164] A schematic of HP's normally closed nickel/silicon bimetal valve was shown earlier in Figure 8.68c (a more detailed view is presented in Figure 8.71b). Resistive heating of the nickel/silicon bimetal causes the membrane deformation and opening of the valve. The competing IC Sensor's

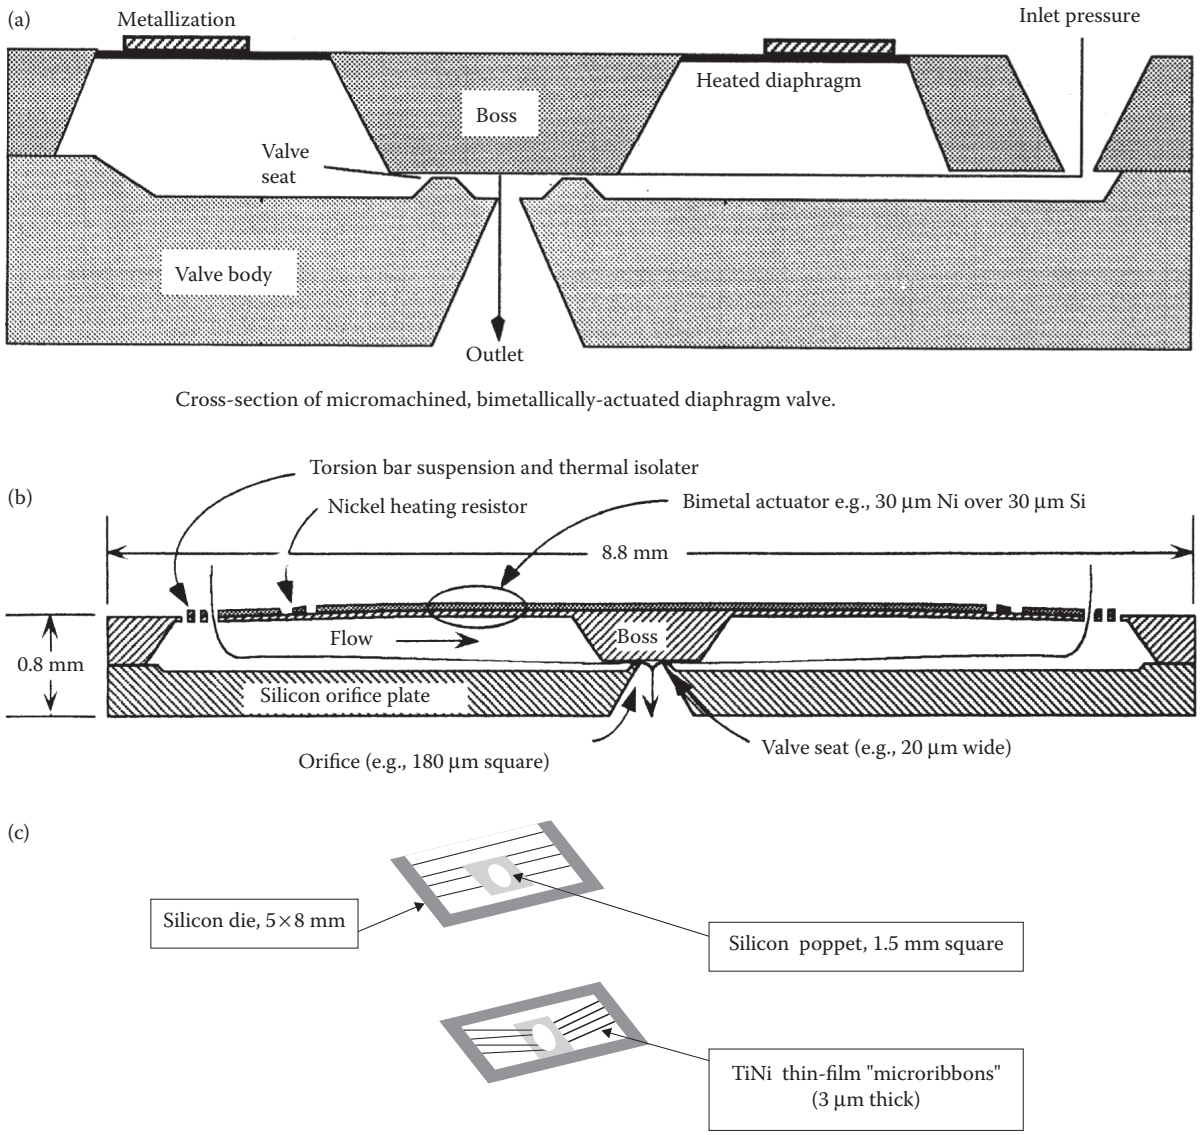

FIGURE 8.71 Commercially available, micromachined, thermally actuated valves. (a) IC Sensor's bimetallic Al/Si valve. (b) Hewlett-Packard's bimetallic Ni/Si valve. (c) The TiNi actuator consists of a rectangle of silicon, 5 mm wide and 8 mm long, that has been partially removed to leave a poppet supported by 8 TiNi thin-film "microribbons." The lower drawing shows these microribbons stretched. When electrical current runs through these microribbons, the shape memory property causes them to contract. The upper view shows the microribbons in their contracted state. The poppet displacement is more than 100 µm, and it can exert a force of as much as 0.5 N (http://www.tinialloy.com/devices.html).

valve (Figure 8.71a) is also a normally closed bimetallic valve but uses an annular aluminum region on a Si diaphragm with integral diffused resistors instead. By varying the electrical power dissipated in the resistors, and thus the temperature of the Si diaphragm, the displacement of a central boss can be controlled.[165] The HP valve exhibits an increase of an order of magnitude in both pressure and flow control capability compared with the IC Sensor's valve. This improvement is made possible by using a torsion bar suspension (see Figure 8.71b) and a nickel-and-silicon bimetal combination, which allows larger valve dimensions and higher stress levels for consequent longer stroke and higher force. For very small structures, this thermal type of actuation becomes an attractive option because of geometric scaling (see comments above and in Volume I, Chapter 6 on the Biot number). The amount of thermal mass decreases as the volume of heated material decreases, and the thermal loss decreases as the thickness of the support structure for the bimetal decreases, while the force per unit area remains high. The normally closed thermopneumatic valve (the Fluistor™) from Redwood Microsystems (now defunct) is shown in Figure 8.68a; in this valve, a liquid-filled cavity, upon heating, forces a silicon diaphragm to lift off the valve seat (a normally open valve is also available from the same company). Although providing a tremendous force (>20 N) through a long stroke (between 50 and 150 μm), this valve is thermally inefficient because of the large volume of heated fluid and is difficult to assemble because of the working fluid in the device. Moreover, it is quite slow (~ 400 ms). A fourth alternative is the normally closed SMA valve from Microflow, sold by TiNi Corporation, which is shown in Figure 8.71c.[166] Sputtered thin-film NiTi is the SMA element and is deformed in tension through an integral BeCu bias spring, pushing it against a valve seat. Passing a small current through the actuator element heats it up, and it regains its original shape, lifting it against the spring from the valve seat and allowing gas to flow. From the point of view of performance, the HP valve stands out; in terms of manufacturability and IC process compatibility, the IC valve has the edge. Redwood Microsystems has gone the furthest in incorporating its valves into higher-level subsystems, including pressure and feedback control, to create a completely electronically programmable pressure regulator. This company has also paid more attention to applying its valves in biomedical instruments carrying fluids.[154,155]

Table 8.19 Salient Points of Thermal Actuators

1. Maximum stroke: 100 μm
2. Maximum speed: 10 s to 1 kHz (low bandwidth; see Figure 8.19)
3. Maximum force: 1–10 mN (high force; see Figure 8.19)
4. Easy to fabricate
6. Footprint: 10 μm to mm
7. Special drive conditions: 1–5 V
8. High power and temperatures
9. Multiaxis operation

Summary: Thermal Actuators

In Table 8.19, we list the salient points associated with thermal actuators. See also Figure 8.14.

Other Actuators and Some Final Actuator Comparisons: Final Comparison

Introduction

In closing this chapter on actuators, we review two more interesting actuator principles, i.e., those based on chemical/electrochemical forces and those based on the quantum mechanical Casimir force, and present some final actuator comparison figures.

Chemical/Electrochemical Actuators

A variety of electrochemical and chemical actuators have been demonstrated. In Volume II, Example 4.3, we reviewed an electrochemical disruptable valve invented by the author (see Volume II, Figure 4.98). Hamberg et al.[167] used electrolysis of water to create pressure on a micromachined membrane. Osmotic pumps use a semipermeable membrane over a pump body to realize a mechanical stroke; the mechanism is clarified in Figure 8.72.[168] A solution in a closed vessel is covered on one side with a semipermeable membrane. A hypertonic solution outside the pump draws solvent from the hypotonic solution inside the pump body, reducing the volume inside and bending the membrane inward. Such an

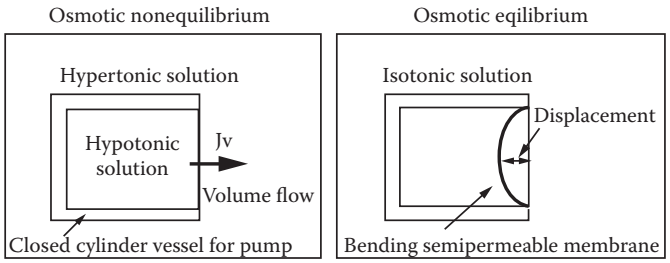

FIGURE 8.72 Mechanism of the osmotic pump. The decrease in volume bends the semipermeable membrane. JV corresponds to the volume flow out of the pump chamber. [After Nagakura, T., K. Ishihara, T. Furukawa, K. Masuda, and T. Tsuda. 1995. In *8th International Conference on Solid-State Sensors and Actuators (Transducers '95),* 287. Stockholm, Sweden.[168]]

osmotic pump was proposed for delivering insulin to a patient, depending on the patient's changing glucose concentration. In this application, the membrane displacement caused by a high glucose concentration in the patient pushes insulin out of the pump into the patient's body.[168]

Also, hydrogels and redox polymers and blends of the two have been used as chemical or electrochemical actuators. Examples include the actuator hydrogel valve in Volume II, Figure 8.15. One of the most useful features of a polymer actuator is that swelling and shrinking of the material can be triggered by a wide variety of external stimuli. This may involve pH, ionic strength, magnetic field, electrical field, etc. A number of these environmentally sensitive or "intelligent" materials are listed in Table 8.20.[169] Most of these polymers exhibit reversible structural modifications upon repeated changes in the external environment. These polymer systems are of great interest as drug delivery vehicles. A Web site describing progress in the general area of electroactive polymers is the WorldWide Electroactive Polymers Newsletter, or Artificial Muscles Newsletter (http://ndeaa.jpl.nasa.gov/nasa-nde/lommas/eap/EAP-web.htm).

In Volume I, Chapter 6, we described a gold/polypyrrole actuator μ-flap (see Volume I, Figure 6.64) as a means of active mixing in the microdomain. A thin Au film (1 μm), covered with a thin layer of polypyrrole, forms an electrochemical actuator. If submerged in an ionic solution, upon application of a bias small solvated cations in the solution move in and out of the redox polymer matrix, swelling and shrinking, respectively, its apparent volume. The volume changes in the polymer generate stresses on the Au layer surface, bending it upward or downward in a "flapping" motion. Movement frequencies in the 1–20 Hz range can be achieved with this type of actuator.

Casimir Forces: A Quantum Actuator

We normally think of a vacuum as space with nothing in it, and we would then also tend to conclude that its energy is zero. But this is inconsistent with the time-energy uncertainty principle that predicts that the energy of a vacuum fluctuates (Volume I, Equation 3.107). It is therefore possible that empty space locally

TABLE 8.20 Environmentally Sensitive Polymers for Drug Delivery

Stimulus	Hydrogel	Mechanism
pH	Acidic or basic hydrogel	Change in pH—swelling—release of drug

does not have zero energy but may have sufficient energy ΔE for a very short time, Δt, to create particles and their antiparticles. This is called the *zero point energy*. Empty space is a seething mass of quantum fluctuations creating virtual particles that recombine and annihilate, just below the threshold of reality (Volume I, Figure 7.29). These fluctuations have been measured as the Casimir effect. The Casimir effect is a small attractive force that acts between two close parallel uncharged conducting plates in a vacuum as illustrated in Volume I, Figures 3.69 and 7.30. Casimir realized that only virtual particles of certain wavelengths can appear between the plates, while those of any wavelength can appear on the outside. Particles other than the photon also contribute a small effect, but only the photon force is measurable. All bosons, such as photons, produce an attractive Casimir force, while fermions make a repulsive contribution.

The attractive Casimir force, F_c, between two plates of area A separated by a distance r can be calculated as follows:

$$F_c = -\frac{\pi^2}{240}\frac{\hbar c}{r^4}A \qquad (8.92)$$

where c is the speed of light. Steve K. Lamoreaux[170] measured this tiny force in 1996 with a torsion pendulum (Figure 8.73). One can quickly establish from Equation 8.92 that two mirrors of 1 cm^2 separated by a distance of 1 μm have an attractive Casimir force of 130 nN. Although this force appears small,

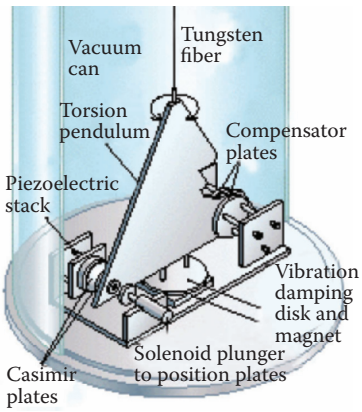

FIGURE 8.73 This experiment by Steve K. Lamoreaux[170] relies on a torsion pendulum. A current applied to the piezoelectric stack tries to move the Casimir plate on the pendulum. The compensator plates hold the pendulum still. The voltage needed to prevent any twisting serves as a measure of the Casimir effect.

at distances below a micrometer, the Casimir force becomes the dominant force between two neutral objects. At separations of 10 nm, the Casimir effect produces the equivalent of 1 atmosphere pressure! Obviously this is a force to reckon with in MEMS and NEMS devices.

As summarized in Table 8.21, Lamoreux's measurement of the Casimir force was followed by many subsequent attempts using MEMS and NEMS actuators to measure this force.

The zero point energy is also connected to Einstein's famous cosmological constant:

$$\Lambda = \frac{8\pi g}{3c^2}\rho \qquad (8.93)$$

where g = gravitational constant
c = speed of light
ρ = energy density of vacuum

Einstein included this term in the equations for general relativity because he was dissatisfied that his equations would not allow for a stationary universe, which was the model of the universe at the time. Soon after Einstein developed his theory, observations by Edwin Hubble (1929) proofed that the universe was expanding. Einstein then abandoned the cosmological constant and called it the "biggest blunder" of his life. The cosmological constant remains of interest though, as observations made in the late 1990s of distance-redshift relations suggest that the universe is accelerating. These observations can be explained by assuming a very small positive cosmological constant in Einstein's equations. The current standard model of cosmology, the Lambda-Cold Dark Matter model (CDM), thus includes the cosmological constant, which is measured to be on the order of 10^{-35} s^{-2}, or 10^{-47} GeV^4, or 10^{-29} g/cm^3, or about 10^{-120} in Planck units.

Final Comparison of Actuator Mechanisms

Finally, in Figures 8.74 and 8.75 we show two very complete figures summarizing the state of the art in actuators by Bell.[171] The first is a figure comparing all types of actuators in terms of maximum displacement versus maximum frequency; the second compares their maximum displacement versus maximum force exerted.

Table 8.21 Attempts Using MEMS and NEMS Actuators to Measure Casimir Force

Investigators	Year	Geometry	Method	Distance Scale (nm)	Materials	Pressure (mbar)	Temp. (K)	Accuracy (%)

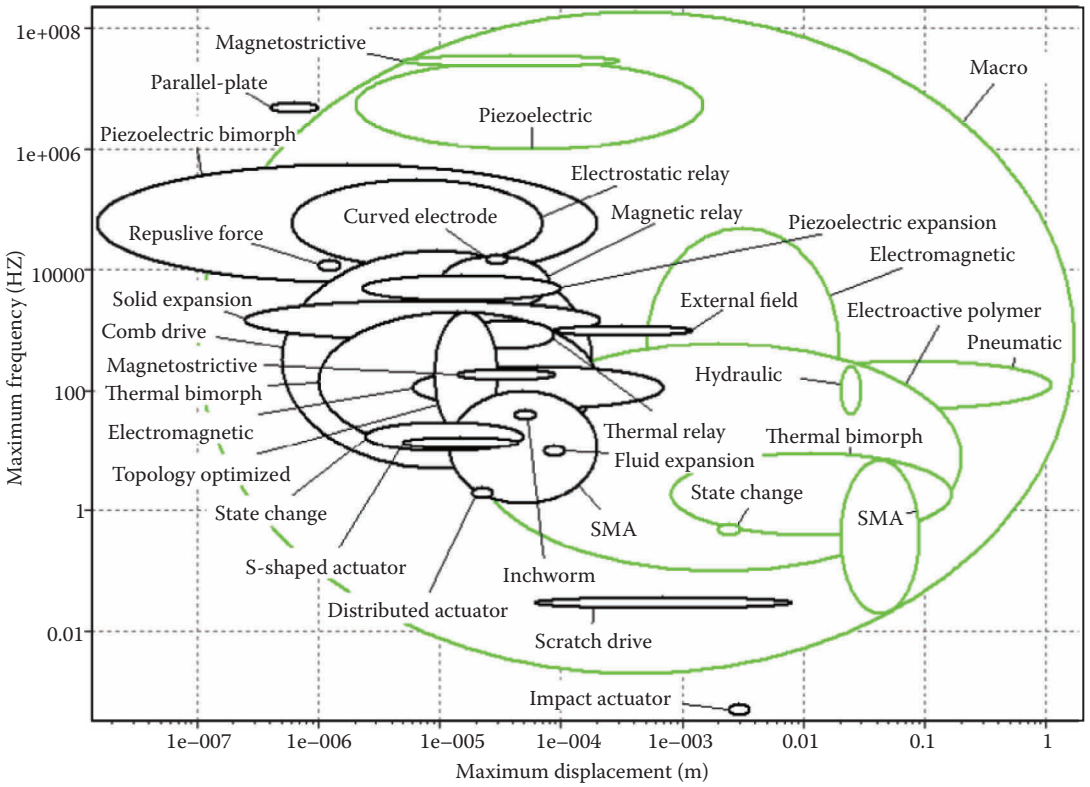

FIGURE 8.74 Comparison of all types of actuators in terms of maximum displacement versus maximum frequency.[171]

Example 8.1: Mass Sensing Actuators

In Volume I, Example 4.1, we analyzed the design criteria for a static mass sensitive piezoresistive cantilever. In that example, we were interested only in the static bending of the cantilever upon mass loading. Here we consider the mass sensitivity of different types of resonators, including cantilever beams. A mass sensitive resonator transforms an additional mass loading into

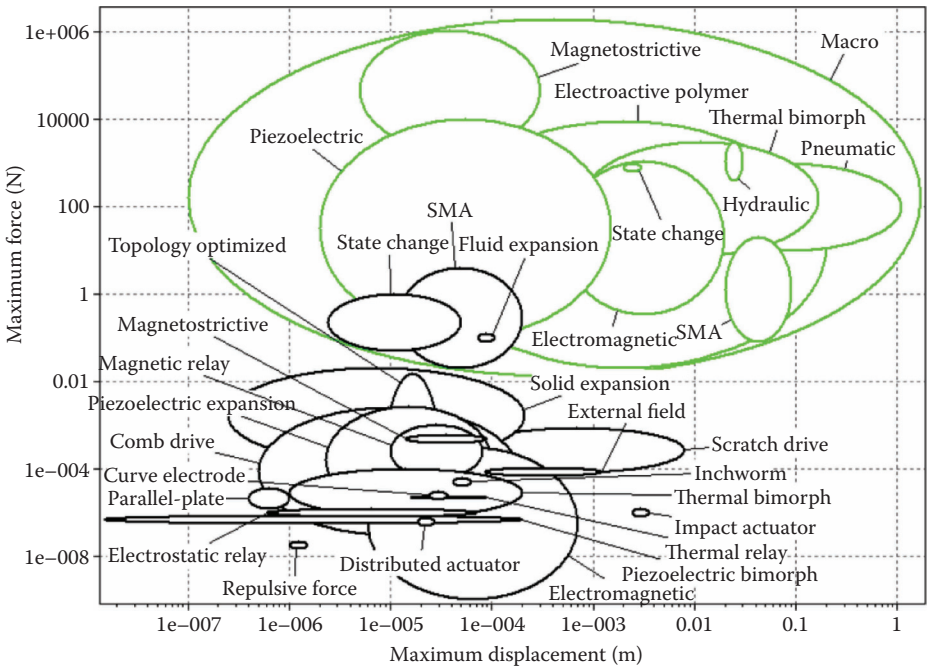

FIGURE 8.75 Comparison of all types of actuators in terms of maximum displacement versus maximum force exerted.[171]

a resonance frequency shift. Resonance frequency shifts of cantilevers can be measured with high precision using optical reflection with a diode laser and a linear position sensitive detector (PSD). The cantilever measuring principle may also be based on the detection of changes in phase, deflection, amplitude, and *Q*.[172] The excitation of MEMS resonators, say a comb drive or a cantilever, is most often realized by electrostatic actuation. The drawbacks of this approach include the relatively high supply voltage and the nonlinearity, linked to the varying distance between the electrodes. An alternative actuation scheme uses the combination of a high-quality piezoelectric thin film with a mechanical resonator. This has several advantages: it avoids the nanometer-size gaps typically required for electrostatic transduction and has a better power handling capability, better impedance handling with electronics, and better potential to reach 10 GHz and above (especially important for very sensitive mass-sensing applications).

Consider as the resonator a uniform beam with a rectangular cross-section, which is fixed at one end and deflected at the other (Figure 8.76). Such a beam experiences lengthwise stress that is compressive below the centerline and tensile above it. The effective spring constant, *K*, of this beam is given by the following:

$$K = EWt^3/4L^3 \qquad (8.94)$$

with *E* the Young's modulus and *W*, *t*, *L* the width, thickness, and length of the beam, respectively. Representative MEMS values for *W*, *t*, and *L* are 20, 0.6, and 100 μm, with a resulting value for *K* of 0.1 N/m.

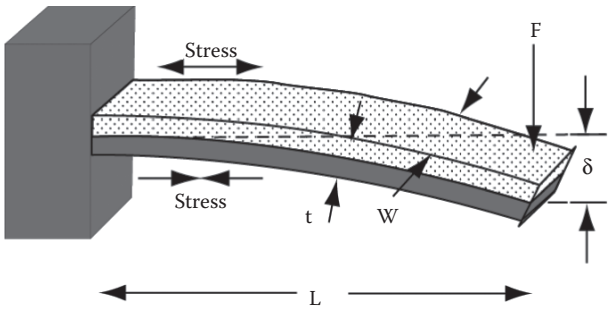

FIGURE 8.76 Stresses in a uniform cantilever beam when deflected.

For this simple cantilever beam the maximum deflection, δ, induced by a weight, W_e, at its free end is given by the following:

$$\delta = \frac{W_e L^3}{3EI} \qquad (8.95)$$

in which *E* and *I* are, respectively, the Young's modulus of the beam material and the moment of inertia of the beam, which is given as $Wt^3/12$. The weight $W_e = Mg$, that is, the mass (*M*) multiplied by the gravitational acceleration (*g*). The stiffness constant, *K*, from Equation 8.94, corresponds to the load/deflection, or $W_e/\delta = 3EI/L^3$, resulting in a natural frequency, f_0, of:

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{3EI}{ML^3}} = \frac{1}{2\pi}\sqrt{\frac{EWt^3}{4ML^3}} = \frac{t}{4\pi L^2}\sqrt{\frac{E}{\rho}} \qquad (8.96)$$

where ρ is the density of the material.* For a Si-based stress-free MEMS cantilever with dimensions of 100 × 3 × 0.1 (*L* × *W* × *t*, in μm), the calculated resonant frequency is 12 kHz (Young's modulus E = 160 GPa); for a NEMS beam of 0.1 × 0.01 × 0.01 (*L* × *W* × *t*, in μm), the frequency is 1.2 GHz. Using a stiffer material (higher Young's modulus *E*) such as SiC (E = 400 GPa), the corresponding numbers are even higher, that is, 19 kHz and 1.9 GHz, respectively— reflecting the higher $(E/\rho)^{1/2}$ in Equation 8.96. In the NEMS range, mechanical devices are almost as fast as today's electronic devices. Making things yet smaller, the ultimate resonant frequency is reached in the THz range, that is, for molecular vibrations.[174] An intermediate frequency of 1.25 MHz was observed for an 8.3-μm-long, 95-nm-thick SiO_2 beam.[175]

In Figure 8.77 we show an example of a set of micromachined single-crystal silicon cantilevers. These beams can be used for real-time, in situ measurements of physical parameters such as viscosity,[176] pressure, density, flow rate and temperature. The latter, for instance, is achieved simply by coating a cantilever with metal on one side to form a bimetal.[177] Mercury vapor,[177] moisture, volatile mercaptans, DNA hybrization,[178] discrimination of single-nucleotide mismatches in DNA,[179] protein conformational changes,[180] and antibody-antigen binding all have been

* For a rigorous derivation, including the case of a thin cantilever that has been metalized with a layer that contributes to the functioning of the device, see Den Hartog.[173]

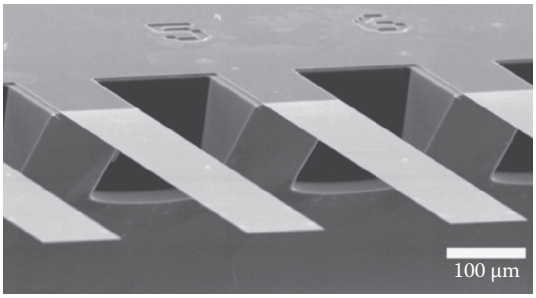

FIGURE 8.77 Scanning electron micrograph of a section of a microfabricated silicon cantilever array (eight cantilevers, each 1 μm thick, 500 μm long, and 100 μm wide, with a pitch of 250 μm, spring constant 0.02 Nm^{-1}. (Reprinted with permission from Fritz, J., M.K. Baller, H.P. Lang, H. Rothuizen, P. Vettinger, E. Meyer, H.-J. Güntherodt, C. Gerber, and J.K. Gimzewski. 2000. Fritz, Massachusetts Institute of Technology Media Lab.[182])

monitored using cantilevers.[181] For chemical and biochemical sensing, the microcantilever surface must be derivatized with chemically selective coatings, perhaps through self-assembled alkanethiols or organosilane films, direct covalent attachment of molecular receptors, dip coating (e.g., polymeric resins), or adsorption/evaporation (e.g., sol-gel matrices).

Under the assumption of negligible variation in spring constant and uniformly distributed mass loading of the beam, Equation 8.96 describes the resonance frequency dependence on mass of the cantilever. Adding a discrete mass, M_d, to the cantilever defines a total effective mass, M_T, of the cantilever-adsorbate system as $M_T = M + M_d$. Equation 8.96 describes the mass dependence of a mass sensing cantilever, in which case the effective mass is that of the cantilever plus an adsorbate. The effective mass of the beam, M, is related to the mass of the beam, M_b, through $M = nM_b$, where n is a geometric parameter, which for a rectangular bar is 0.24.[183] This results in an expression for the resonant frequency given by the following:

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{EWt^3}{4M_TL^3}} = \frac{1}{2\pi}\sqrt{\frac{EWt^3}{4L^3(M_d + 0.24WtL\rho)}} \tag{8.97}$$

where ρ is the density of the cantilever. To compare the mass sensitivity, S_m (given by Equation 8.64), of a cantilever sensor to that of other gravimetric devices, see Table 8.9.

In a case where mass loading is distributed evenly over the cantilever surface, S_m, as noted in Table 8.9, is given by the following (in Table 8.9, d was used for thickness instead of t).

$$S_m = \frac{1}{\rho t} \tag{8.98}$$

The positive sign indicates that, as mass is added, the resonant frequency increases, corresponding to the increase of the cross-sectional thickness of the beam. For an end-loaded cantilever (mass only allowed to accumulate in a small area at the free end of the beam) this results in:

$$S_m = \frac{-\xi}{2\rho(\xi t_d + 0.24t)} \tag{8.99}$$

where ξ and t_d are the fractional area coverage and thickness of the deposited mass, respectively. The negative sign denotes that the frequency is decreasing with increasing mass piling up.

From the above we conclude that for mass sensing with a microcantilever, a uniform mass loading is preferred. From Equations 8.98 and 8.99, it is further advantageous to make the cantilever as low density (ρ) and as thin as possible (t). Dramatic further improvements in analytical figures of merit can be achieved by scaling the cantilever size down to the nanoscale.

In Figure 8.78 we compare the size of a typical quartz crystal microbalance (QCM) transducer, with a minimal volume of 80 mm^3, with an array of ten micromachined cantilevers (e.g., based on silicon nitride) that requires as little as 0.001 mm^3 of volume.

From Table 8.9 cantilevers are much more sensitive than quartz microbalances and are

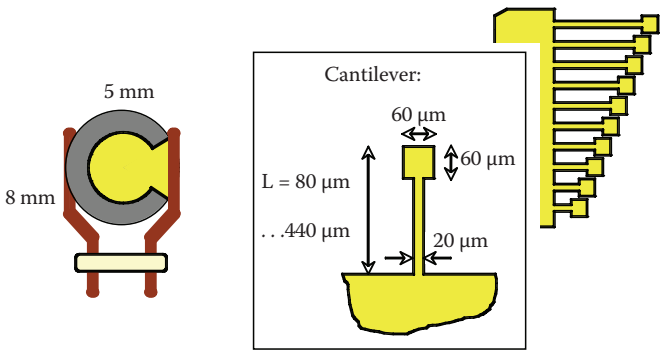

FIGURE 8.78 Size comparison of a quartz crystal microbalance and a micromachined array of cantilevers.

easier to downscale. Nanomechanical resonators enable the measurement of mass with extraordinary sensitivity. Samples as light as 7 zeptograms have been weighed in vacuum with cantilevers.[184] Resolving such small mass changes requires the resonator to be very light with a high *Q*. In solution, viscosity severely degrades both of these characteristics, preventing many sensing applications where fluid is required. One needs to excite with a positive feedback loop of a piezoelectric or measure in air or vacuum. FBARs, we saw earlier, can be downscaled more easily than BAWs, and for similar size they are even more sensitive than cantilevers (see Table 8.9).

An alternative approach, avoiding the viscous damping problem, is to use a static formulation, pioneered by Thundat et al. from Oak Ridge National Laboratory,[177] and involves the measurement of bending induced by the adsorption of molecules onto a thin microcantilever that has two chemically different surfaces. The Thundat et al. approach was covered in Volume I, Chapter 4 (Example 4.1).

Burg et al. pioneered yet a different approach to eliminate viscous damping by placing the solution inside a hollow resonator that is surrounded by vacuum.[185] This group demonstrated that suspended microchannel resonators can weigh single nanoparticles, single bacterial cells, and submonolayers of adsorbed proteins in water with subfemtogram resolution (1 Hz bandwidth). The combination of the low resonator mass (100 ng) and high-quality factor (Q = 15,000) enables an improvement in mass resolution of six orders of magnitude over a high-end commercial quartz crystal microbalance. This development gives access to intriguing applications, such as mass-based flow cytometry, the direct detection of pathogens, or the nonoptical sizing and mass density measurement of colloidal particles.

There are several (near) commercial biosensors based on microcantilever structures, as well as companies aiming at commercializing such products (e.g., Protiveris, Graviton, Concentris and Cantisens® Research). The current trend in SAW and QCM devices is to work at higher frequencies for better sensitivity, and in silicon MEMS, micro- and nanocantilvers are replacing quartz devices, as they are easier to integrate and easier to make into many device arrays. The key strength of all these devices is that they hold the promise of label-free measurements. In Chapter 10, this volume, we will also see that the RF-MEMS community is hard at work trying to replace quartz and AlN resonators with silicon MEMS-based oscillators.

Questions

Questions and answers by Dr. Marc Madou, assisted by Mr. George O'Quinn, UC Berkeley

8.1: Fill in the blank with the correct word.
- (a) Piezoelectric materials produce _____ when they are deformed by a force.
- (b) Silicon is _____ piezoelectric.
- (c) Viscosity of a fluid is the tendency of the fluid to _____ .
- (d) Large field strength can be used to produce large _____ with smaller _____ .
- (e) _____ is the major loss mechanism in microactuators.
- (f) Shape memory alloys recover the shape they are given when they are heated to a temperature that is higher than the _____.

8.2: What is the difference between a sensor and an actuator?

8.3: What is the underlying principle of ferrofluids (FF) and how do they differ from magnetorheological fluids (MR)?

8.4: Describe, using equations, why one might prefer a parallel-driven parallel plate capacitor in an electrostatic actuator over a vertical-driven one?

8.5: Prove that the snap voltage V_{snap} in a parallel plate capacitor is given by 1/3 g_0, where g_0 is the initial gap spacing (with V = 0).

8.6: Make a table listing corresponding mechanical and electrical equivalent circuit components.

8.7: Suggest a normally closed valve technology based on phase-change of a material that

works for both vapors and liquids and does not require power to remain closed but only to open.

8.8: What transduction principles are used in biosensors?

8.9: What is the difference between a self-exciting and a modulating sensor? Give at least one example of each used to sense the same quantity.

8.10: Describe different methods to levitate and move a biological cell to a desired spot on a glass slide.

8.11: Why are wobble motors effective when small, yet ineffective when large, and what role does friction play in a wobble motor?

8.12: Explain the Seebeck effect, Peltier effect, Thomson effect, and Joule heating. How are they important to thermoelectric devices?

8.13: What are the characteristics of shape memory alloy (SMA) actuators that cause them to have a slower response time, but higher force than piezoelectric and electrostatic actuators?

8.14: What is the main difference between piezoelectricity and ferroelectricity?

8.15: How are Cooper pairs formed?

8.16: Why do good conductors make poor superconductors?

8.17: Why is the Casimir force an important consideration in MEMS and NEMS?

8.18: Explain magnetostriction and compare it to the piezoelectric effect.

8.19: Name five mechanical measurands.

Introduction

In this chapter we consider power and brains in miniature devices. We analyze the challenges and promises of powering miniaturized devices and of the miniaturization of power sources themselves. The power section starts with a comparison of onboard energy sources, such as batteries, capacitors, fuel cells, internal combustion engines, and solar cells. Next, we consider energy scavenging methods, such as taking advantage of environmental vibrations or thermal gradients.

Miniaturization of power sources scales disadvantageously, as the specific energy (energy per volume unit: l^3) of the power source determines the volume for a given application. That volume, besides the active materials (say, Li in a Li-ion battery), must also include packaging, and packaging efficiency degrades as the power source gets smaller.

As in the case of cell phones, personal digital assistants (PDAs), distributed sensor networks, portable computers, etc., small, lightweight, and long-lasting energy sources are one of the most urgently needed MEMS and NEMS breakthrough technologies. A pertinent quote from *Wired* magazine in April 2004 reads, "If we don't do something about increasing

battery life, we're toast. The biggest impediment to our technological future isn't extending Moore's law. No, the biggest challenge to progress is much more ordinary: It's battery life."[1]

Micro- and nanosystems require even smaller power sources, as weight and volume of onboard energy sources are disproportionately large compared with the systems they power. The roles of energy storage and energy dissipation in microsystems differ considerably from the world of practical daily experience. Designing micro- and nanosystems demands close examination of energy budgets and taking advantage of the merits of smallness as well as minimizing its adverse effects. In Figure 9.1 we compare progress made in improving processors, hard disk drive (HDD) capacity, and battery energy stored. Compared with the other technologies, progress in battery improvement is obviously much more sluggish, with a growth of, at most, 2–3% per year: there is obviously no Moore's law for batteries.

The section on power in MEMS and NEMS should help the reader in choosing a preferred power source for his or her MEMS/NEMS device.

We also consider the implementation of computing power or "brains" in miniaturized systems. After a short summary of current and projected computer technology and its comparison with nature's computers, we consider the latest developments in a field closely related and important to microrobotics: artificial intelligence (AI). We will discuss how both bottom-up and top-down approaches to AI might impact miniaturization technology. Complexity theory and artificial life are examples of bottom-up approaches to building AI that feature the self-organizing or emergent properties touched upon in Chapter 3. Artificial neural networks represent a bottom-up approach to developing brains heavily dependent on learning cycles. Electronic noses and tongues have already been developed on the basis of such neural nets (see Chapter 10). As in the case of machining, we will learn that bottom-up approaches for embedding intelligence in miniature devices are gaining more and more interest.

Power in MEMS and NEMS

Onboard Energy Sources

Introduction

Onboard energy sources for MEMS devices may include radioactive sources, batteries, capacitors, fuel cells, internal combustion engines, solar cells, etc. Combustion processes for electrical power generation provide advantages over onboard batteries, even when the low conversion efficiency in the combustion process from thermal energy to electrical energy is taken into account. For example, hydrocarbon fuels provide an energy storage density between 40 and 50 MJ/kg, whereas modern nickel metal hydride batteries, commonly used in laptop computers, provide only 0.4 MJ/kg. Thus, even at only 4% conversion efficiency from thermal to electrical energy, hydrocarbon fuels provide about five times higher energy storage density than batteries.

There has been a lot of attention given recently to MEMS and even NEMS power sources. The goal is to put as much energy as possible in the smallest amount of space. To form an idea of what is achievable with known power systems, we list the energy one can store in 1 mm^3 of various power systems in Table 9.1. From this table, the highest energy density available is from a radioactive source, but such sources may never be practical for consumer applications because of environmental and safety concerns (although americium is used as the current source

Table 9.1 Energy Stored in 1 mm^3

Power capacitor	4 μJ/mm^3	1 μW for 4 s
Thick-film battery	1 J/mm^3	270 μW for 1 h
Thin-film battery	2.5 J/mm^3	0.7 mW for l h
Solar cell (1 × 1 × 0.1 mm^3)		0.1 mW
Gasoline	300 J/mm^3	3 mW for 1 day
180 Ta ($T_{1/2}$ = 8 h)	≈1 MJ/mm^3	34 W
178 Hf ($T_{1/2}$ = 31 years)	>10 MJ/mm^3	160 mW

in some fire alarms). Chemical energy in the form of batteries provides the next highest density. Solar light, at noon on a sunny day, gives us 100 mW/cm^2 (office lights are 7.2 mW/cm^2). Collectors of solar light work with varying efficiency; single-crystal Si provides a 14–30% efficient conversion of light to power. Polysilicon provides about 10–15% efficiency, and organic dyes are 5–10% efficient.

Future stand-alone microsystems will almost surely employ hybrid strategies, using low levels of power for low-level activities and quick bursts of energy, perhaps relying on a capacitor, for computing, communication, or maneuvering.

MEMS and NEMS Batteries, Capacitors, Fuel Cells, Combustion Engines, and Solar Cells

Batteries

To judge the benefits and problems associated with different battery technologies, some general properties of batteries must be introduced. It is usually desirable that the amount of energy stored in a given mass or volume of active battery material is as high as possible. To compare the energy content of batteries, the terms *specific energy* (expressed in Wh/kg) and *energy density* (in Wh/L) are used, whereas the rate capability is expressed as *specific power* (in W/kg) and *power density* (in W/L). To reach the goal of a high specific energy and energy density, two fundamental requirements must be met by the battery electrode materials: 1) a high specific charge (in Ah/kg) and charge density (in Ah/L), i.e., a high number of available charge carriers per mass and volume unit of the material; and 2) a high (positive electrode) and low (negative electrode) standard redox potential of the respective electrode redox reactions, leading to a high cell voltage (see also Volume I, Chapter 7). Moreover, in rechargeable batteries (also called *reversible* or *secondary batteries*), reactions at both negative and positive electrode have to be highly reversible to maintain the specific charge for hundreds of charge/discharge cycles. With an assumed cycling efficiency of even 99% in each cycle, the available specific charge after 100 cycles would be only ~37% of the initial value (after 500 cycles, less than 1%), and electrode materials should thus combine high specific charge with good rechargeability.

In Table 9.2 we list primary and secondary batteries for onboard power systems, and for comparison we also included data on microfuel cells and

Table 9.2 Examples of Onboard Power Systems

On Chip			
Power Sources	**Energy Density (Wh/kg)**	**Wh/L**	**Power Density (W/kg)**
Primary batteries			
Zinc air	200	1050–1560	150
Zn-Cl_2	150	100–180	90
Alkaline	125–225	150–440	
Silver Oxide	155–285	250–500	
Lithium	100–200	340–500	>200
Secondary batteries			
Lead-acid	30–40	40	30–40
Ni-Cd	200	170	150–200
NiMH	150–200	250	150
Li–ion	100	300	200
Microfuel cell		4000	
Ultracapacitors		13–28	200

ultracapacitors. The specific energy (energy per volume unit) of the onboard power sources listed in Table 9.2, determines the proper active volume for a given application. If the volume of the packaging is taken into account, energy volume densities of primary lithium batteries may reach 340–500 Wh/L; these batteries generate the highest specific energy of any commercially available battery. If we assume that the average power consumption of a MEMS device is 100 mW, we need slightly more than 1 cm^3 of lithium battery to last for 1 year, assuming we can use 100% of the charge in the battery. The energy density of rechargeable batteries is typically less than half of that of primary batteries, so in that case we need to be recharging every 3–4 months. Today, commercially available batteries are obviously too big for most MEMS devices, and they are even too big for many mobile consumer applications.

An important technical challenge that arises in considering downscaling batteries, besides the obvious fact that their capacity scales as l^3, is that battery packaging efficiency scales poorly in the microdomain: there is relatively more packaging in smaller batteries than in large ones. What is needed, then, in the microbattery arena is a set of new packaging strategies, new materials, and new manufacturing techniques. In order to be able to make an onboard micropower source using MEMS technology, one also expects that the materials involved are compatible with microfabrication processes (e.g., being stable under vacuum conditions; no liquid electrolytes), that the battery is rechargeable (because its life cycle will be short), and that the reaction products are compatible with the MEMS device.

In terms of commercially available batteries for MEMS, Li primary and Li-ion reversible batteries are the two most important choices today. In lithium primary batteries, the anode, consisting of high-purity lithium, may be combined with many different cathode materials, resulting in different voltages ranging from 1.5 to 3.9 V. For electrolyte, batteries contain organic solvents in which lithium salts are dissolved or they feature solid polymers that also may function as electrolytes. Beyond the button Li batteries 4.8 mm (diameter) by 1.4 mm (high) used in watches and cameras, progress in miniaturizing high-energy-density power sources has been limited. Button Li cells are now the best available primary energy sources for microsystems. The basic principle of rechargeable Li-ion batteries is electrochemical intercalation and de-intercalation of lithium in both electrodes. As we noted above, an ideal secondary or reversible battery has a high-energy capacity, fast charging time, and long cycle life. The capacity is determined by the lithium saturation concentration of the electrode materials. Many materials combination have been researched, and an often touted approach is the use of carbon nanotubes (CNTs). The highest Li concentration can be stored in CNTs if all the interstitial sites (inter-shell van der Waals spaces, inter-tube channels and inner cores) are accessible for Li intercalation. Nalimova et al. proved that two Li atoms per C atom can be stored in multiwall carbon nanotubes (MWCNTs) under a high pressure of 6 GPa.[2,3] This is a very high Li loading, but it involves a chemical reaction, not an intercalation, and its usefulness for a battery is not established. Gaucher et al. reported high degrees of irreversible (500 mAh/g) and reversible (450 mAh/g) insertion of lithium ions in MWCNTs in an aprotic medium.[4] They noticed that the structure of the MWCNTs plays an important role in specific capacity and cycle stability. The capacity of less-graphitized MWCNT was higher than that of the well-graphitized MWCNT, although the latter exhibited better cycle stability and charge/discharge rates.[4] In spite of such interesting behaviors of CNTs as the host of lithium intercalation, their large irreversibility capacity and their poor discharge curves relative to those of lithium metal leave the material not satisfactory yet for commercial applications.

Batteries and fuel cell materials deposited with integrated circuit (IC) technologies on the device substrate itself remain in the research stage.[5] Often, the thin-film materials deposited in constructing those batteries, such as Li, TiS_2, V_2O_5, etc., prove incompatible with the IC process, and the prospect of integrating them with ICs remains remote. Ultrathin, solid-state Li cells—"energy paper"—are beginning to emerge. Kanebo introduced the polymeric polyacenic semiconductor (PAS)-based battery as far back as 1993. The polymer PAS film in the battery is only 200 μm thick and has an active surface area of 2200 m^2/g. It serves as the anode, and the cathode is

lithium based. The voltage is 3.3 V, corresponding to 3 Ni-Cd elements in series. Unfortunately, the energy density, taking the complete, packaged battery into account, is only 5.5 Wh/L.[6]

If a MEMS device uses 10 μW of power continuously, in a day it will consume ~1 J of energy. Since the energy density for Li-ion thin-film systems is in the range of ~2 J mm^{-3}, matching or exceeding standard commercial lithium-ion systems, it would appear that this battery fits the task. In reality, this is not so: thin-film batteries, as shown in Figure 9.2, are two-dimensional (2D) devices and are necessarily thin in order to prevent power losses typically associated with the slow transport of ions, and this form factor leads to a low capacity per mm^2. The energy per unit area as reported for several lithium thin-film batteries ranges from 0.25 to ~2 × 10^{-2} Jmm^{-2};[7] consequently, with a typical device thickness on the order of 15 μm, a thin-film battery would require a significant amount of area in order to supply 1 Jmm^{-3}.

The real question then becomes whether a thin-film battery can supply the energy that the MEMS device requires within the constraints of the areal "footprint" available for the battery. Unfortunately, a thin-film battery of 1 mm^2, despite having an excellent energy per unit volume, falls far short of being able to power a typical MEMS for more than one day. If the areal footprint is made 100 times larger (at 1 cm^2), the thin-film approach becomes more acceptable,[7,8] These important consequences of the 2D nature of thin-film batteries are frequently overlooked. The calculation by Koeneman et al.,[9] for example, ignored the 2D character of thin-film batteries when they concluded that these batteries could carry out some 60,000 actuations of a "smart bearing."[7] When the actual area available for the power source on the device is considered, only about 1200 actuations are possible. In order to power devices with limited real estate and maintain a small areal footprint, batteries must somehow make better use of their thickness dimension.[7]

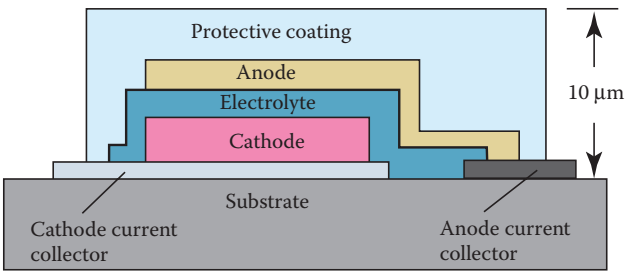

FIGURE 9.2 Example thin-film battery.

In recent years there has been a growing realization that improved microbattery performance can be attained by configuring the electrode materials currently employed in 2D batteries into micro-three-dimensional (μ-3D) architectures (high-rise batteries). In this approach, cell structures are designed to maximize power and energy density while maintaining short ion transport distances.[7] There are several possible architectures that can achieve this same goal, but an underlying principle in all μ-3D batteries is that the transport between the electrodes remains one-dimensional at the microscopic level, while the electrodes are configured in complex nonplanar geometries in order to increase the energy density of the cell within the same footprint area.[7,10]

Detailed calculations by Long et al.[7] show that microbatteries configured as μ-3D structures can readily achieve 1 Jmm^{-2}, the amount required to power a typical MEMS device for a day. Perhaps the most obvious μ-3D design is one consisting of interdigitated electrode posts, shown in Figure 9.3a. The anode and cathode consist of arrays of rods separated by a continuous electrolyte phase. The spatial arrangement of the anode and cathode arrays determines the current-potential distribution. The short transport distances lead to a much lower ohmic resistance as compared with traditional planar battery configurations. The molecular diffusion equation indicates that diffusion over a 10-μm distance is 1 million-fold faster than diffusion over a 1-cm distance, since $x = (2D\tau)^{1/2}$ (Volume I, Equation 6.100), where D is the diffusion constant and τ the time required for a molecule to diffuse over distance x. Thus, μ-3D configurations with narrow electrode posts offer a means of maintaining "short" diffusion distances, thereby increasing the power capacity of the battery. For example, Hart et al. first consider a thin-film 2D battery that comprises a 1-cm^2 area for both anode and cathode, each 22.5 μm thick and separated by a 5-μm-thick electrolyte.[10] The total volume of electrodes and electrolyte in this case is 5 × 10^{-3} cm^3. It is relatively straightforward

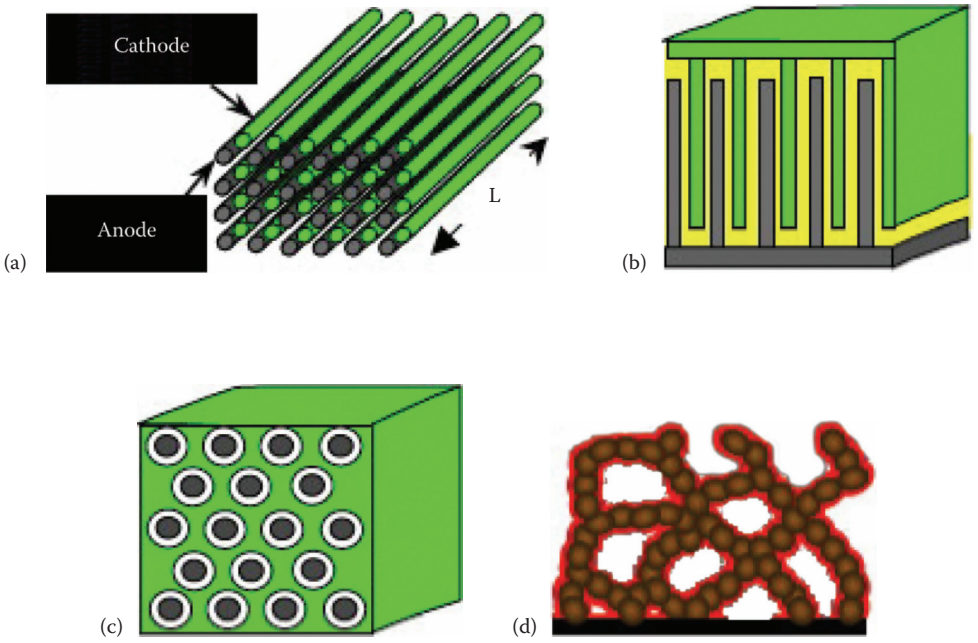

FIGURE 9.3 Examples of prospective three-dimensional architectures for charge-insertion batteries. (a) Array of interdigitated cylindrical cathodes and anodes; (b) Interdigitated plate array of cathodes and anodes; (c) Rod array of cylindrical anodes coated with a thin layer of ion-conducting dielectric (electrolyte), with the remaining free volume filled with the cathode material; (d) Aperiodic "sponge" architectures in which the solid network of the sponge serves as the charge-insertion cathode, which is coated with an ultrathin layer of ion-conducting dielectric (electrolyte), and in which the remaining free volume is filled with an interpenetrating, continuous anode.[7]

to calculate then that a corresponding μ-3D array battery (see Figure 9.3) with a series of 5-μm-radius interdigitated cathodes and anodes, a 5-μm surface-to-surface electrode spacing, and occupying the same total volume (i.e., 5×10^{-3} cm^3) contains only about 39% of the energy capacity of the thin-film 2D design. The lower-energy capacity is due to a higher percentage of the total volume being occupied by the electrolyte. On the other hand, the active cathode and anode surface areas in the three-dimensional (3D) design are 3.5 cm^2 each, significantly larger than the 2D design. There are some other intriguing advantages of the μ-3D design that are not directly reflected in the above numbers. For instance, the transport length scale in the thin-film 2D battery is 350% larger than in the 3D design. This means that the μ-3D design is significantly less susceptible to ohmic losses and other transport limitations. To achieve equal transport length scales in the 2D design would require a 350% increase in the areal footprint in order to maintain equal cell volume, a significant disadvantage in employing these devices in MEMS and microelectronic applications. While the above comparison of 2D and μ-3D designs indicates that the μ-3D cell has an inherently lower-energy capacity per total cell volume, in fact, the capacity of the 3D design can be increased without limit by increasing the battery height, without sacrificing the small area footprint or high-power density.

For an example of this type of μ-3D electrode configuration, see the carbon-MEMS (C-MEMS) battery in Figure 5.18. This type of battery is being developed by Enevate (http://www.enevate.com/).

Capacitors

Rechargeable and disposable (primary) batteries, reviewed above, use a chemical reaction to produce energy. The problem is that after many charges and discharges, even a rechargeable (secondary) battery loses capacity, to the point where the user has to discard it. However, capacitors contain energy stored in an electric field between charges on two metal electrodes separated by a dielectric. Capacitors charge faster and last longer than normal batteries, and their reversibility, absence of polarity, and extended lifetime make them an attractive alternative for power in microsystems. They are useful for on-chip power conversion, but their energy density

is too low to be a real secondary storage component. Electrochemical capacitors improve that perspective; with an energy density on the order of 75 J/cm^3, they are a good potential for secondary storage.

Electrochemical capacitors are called by a number of names: *supercapacitors*, *ultracapacitors*, and *electrochemical double-layer* (ECDL) *capacitors*. Typically, supercapacitor devices consist of two electrodes and an insulating material that separates the electrodes. The insulator prevent electrical contact but allows ions from the electrolyte to pass through. At each electrode, there exists a dipole layer, the so-called *ECDL*. Typically ~0.4 nm thick, the ECDL acts as a capacitor if the potential difference across it is less than that needed to dissociate the electrolyte (into hydrogen or oxygen in the case of water). If the electrolyte is water, this restricts the voltage to 1.23 V, but higher voltages of 2.3 V are possible by using a nonaqueous electrolyte, such as tetraethyl ammonium fluoroborate in propylene carbonate. The capacitance is given by $C = \varepsilon A/d$, where ε is the dielectric constant, A is the electrode surface area, and d is the ECDL thickness. The electrodes are made of materials with a high effective surface area, such as porous metal oxides (e.g., IrO_x), porous carbon, or carbon aerogels, in order to maximize the surface area, A, of the double layer and to achieve a small double layer thickness, d. By choosing and fabricating electrodes with extremely high surface area A (e.g., 1000 m^2/g or greater) and a small d, very large capacitances are achievable (e.g., 1000 F). Carbon nanotube filaments can further increase the surface area of the electrodes and allow capacitors to store yet more energy. Single-walled carbon nanotubes (SWNTs) have the largest surface area to volume ratio of any carbon material, 3000 m^2/g, as all their atoms are on the surface, and they make for the ultimate electrode material. This advantage is used for energy storage in nanotube supercapacitors.[7]

The performance of supercapacitors is judged in terms of their energy density (per unit volume) or $\frac{1}{2}CV^2$ and power density or V^2/R, where R is their series discharge resistance. Another advantage of CNTs in this regard is that they have a much lower resistance than the often-used activated carbon, which could greatly increase their power density. The limiting factors are contacting CNTs to the electrode backing and having the ability to do this at low temperatures and at a low cost, as the competing activated carbon is very cheap.

Since it is possible to carbonize photoresist materials, make them porous, and charge them, it is possible to integrate ultracapacitors on ICs (see C-MEMS in Chapter 5). The most challenging technical issue, just as in the case of a battery, is packaging. Supercapacitors and batteries incorporate very corrosive and reactive materials, making the challenge even more daunting.

The performance of supercapacitors can be gleaned from the *Ragone plot*, as shown in Figure 9.4. A Ragone plot is a log-log plot of the specific power (W/kg) versus the specific energy (Wh/kg).

As can be seen from this plot, supercapacitors or ultracapacitors bridge the gap between capacitors and batteries and have the ability to store greater amounts of energy than conventional capacitors, and they are able to deliver more power than batteries. Supercapacitors also possess a number of desirable qualities that make them an attractive energy storage option: they store and release charge completely reversibly, they are extremely efficient and can withstand a large number of charge/discharge cycles, they can store or release energy very quickly, and they can operate over a wide range of temperatures.

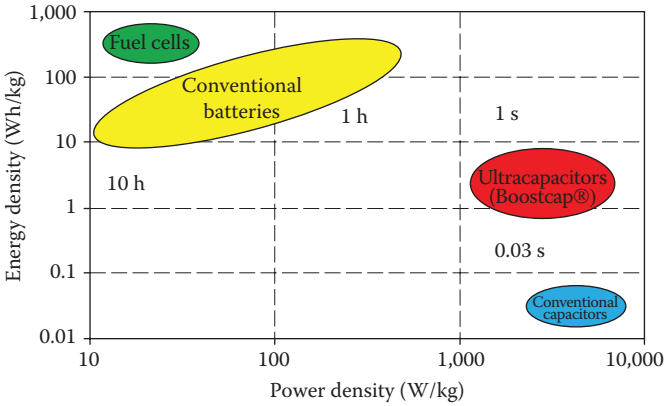

FIGURE 9.4 Ragone plot. The power density versus energy density plot distinguishes various electricity storage systems. Batteries are high-energy density but low-power density, whereas normal capacitors are low-energy density but high-power density. Li^+ batteries have the highest energy density of any battery. Supercapacitors have a high-energy density and high-power density and are intermediate between normal capacitors and batteries. See http://www.tecategroup.com/ultracapacitors/maxwellboostcaps.php.

Fuel Cells

Introduction

Two major challenges of our times are the shrinking of available fossil energy resources and climate change associated with global warming. With humans consuming carbon-based fuels (carbon, natural gas, coal, and tar shale) faster than they can be replaced, yet another "oil war" making the daily news, GM still selling 15–20,000 Hummers a year, and Tata planning to sell millions of its new Nano cars, independence from fossil fuels has finally again become what former President Jimmy Carter called the "moral equivalent of war."

One of the often advanced solutions to the energy crisis is to replace fossil hydrocarbon-based energy with the energy from carbon-free sources such as the sun, nuclear energy, or the hot interior of the earth and use hydrogen as the energy carrier. Hydrogen can be produced by hydrolysis of water using energy from carbon-free sources, and the hydrogen thus produced can serve as fuel in fuel cells to generate electricity, either stationary or mobile.

Fuel cells, discovered in the 1850s, are batteries with renewable energetic materials (fuels) (see inset in the heading of Part II and Figure 9.5). The electrodes in a fuel cell do not take part in the cell reactions they act as reaction sites only. The basic reaction in a fuel cell is reversed electrolysis, or:

$$2H_2 + O_2 = 2H_2O \qquad \text{Reaction 9.1}$$

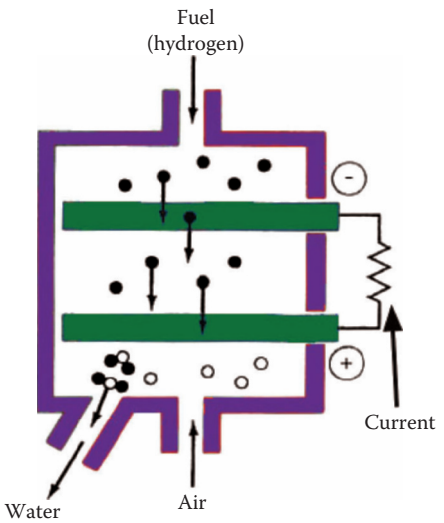

FIGURE 9.5 Schematic of a fuel cell.

Electricity is produced in an anode reaction:

$$H_2 = 2H^+ + 2e^- \qquad \text{Reaction 9.2}$$

and a cathode reaction:

$$\tfrac{1}{2}\, O_2 + 2H^+ + 2e^- = H_2O \qquad \text{Reaction 9.3}$$

Fuel cells can help us generate cleaner power from conventional sources more efficiently and can be viewed as a temporary energy solution until we can harvest more renewable resources (solar, wind) and/or or more powerful sources (fusion) directly.

Differences in electrolytes used determine the type of fuel cell:

- Phosphoric acid fuel cell (PAFC)
- Proton exchange membrane fuel cell (PEM, SPE™, and PEFC)
- Solid oxide fuel cell (SOFC)
- Molten carbonate fuel cell (MCFC)
- Alkaline fuel cell (AFC)

There are quite a few positive fuel cell attributes to enumerate. Power and energy density of a fuel cell are higher than in batteries [e.g., methanol (1550 Wh/L, 1738 Wh/kg) versus lithium-ion (450 Wh/L, 185 Wh/kg); see also the Ragone plot in Figure 9.4]. Fuels used in fuel cells typically have much higher (approximately 10×) energy densities than their battery counterparts, and to increase the power density of a fuel cell, one only needs to increase the surface-to-volume ratio within the cell. The latter is a much simpler task than engineering new material chemistries for batteries. There is no lengthy recharging, as fuel cells are rapidly refueled; instead of charging a battery for an extended amount of time, a fuel cartridge is inserted. The energy conversion process in fuel cells is simpler, and there is an unlimited access to active electrochemical material (fuel), while the amount of active materials accessible for energy conversion in batteries is limited to their volumetric energy density. Fuel cells feature negligible self-discharge, are clean and environment-friendly, and have an unlimited cycle stability. Costs of fuel cells are coming down: through sophisticated engineering the amount of expensive platinum required for catalysts is being lowered, and new manufacturing

processes are being introduced. While the cost per Joule ($/J) has gone up for energy-dense batteries (e.g., NiCd weighs 0.5 kg, lasts 1 h, and costs $20, and a comparable Li-ion battery lasts 3 h but costs more than four times more), the cost of a comparable fuel cell that lasts 30 h has gone down (to perhaps <$5).

Disadvantages of fuel cells compared with batteries are lower efficiency (up to 50–60%, compared with about 90% for Li-ion batteries) and the need for peripherals such as pumps, humidifiers, fuel processors, power conditioners, etc. These peripherals have to do with the need to obtain hydrogen from traditional fuels (oil, coal, wood, propane, natural gas, ethanol, etc.), to store fuels and hydrogen (the storage medium), and to manage heat and water (both products of the fuel cell reaction) and power (e.g., convert DC to AC). A typical process to obtain hydrogen is steam reforming, which can process methane into hydrogen (research and development is under way to also reform diesel, gasoline, ethanol, etc.). The basic steam reforming reaction is as follows:

$$CH_4 + 2H_2O = 3H_2 + CO_2 \qquad \text{Reaction 9.4}$$

Intermediate steps in this reaction produce CO, which is reacted to form CO_2. The reaction also requires catalysts to speed up reaction rates, and sulfur compounds must be removed to protect those catalysts.

In Table 9.3 we present a summary of stationary fuel cells (data are from 2003). Fuel cells are still

Table 9.3 Summary of Stationary Fuel Cell Products

too expensive, and in order to introduce them into the huge mobile market, their miniaturization and the integration/simplification of the accompanying peripheral gear is a must (see next section).

Microfuel Cells

Introduction

There are many reasons why one might want to make a miniature fuel cell. To begin with, small fuel cells, especially when they come with less or size-reduced peripheral equipment, will make many more applications possible (e.g., power for mobile phones, iPods, laptops, etc.). The comparison between 2D and μ-3D batteries carried out earlier (see Batteries) can be extended to 2D and μ-3D fuel cells. From simple theoretical considerations, for a specific μ-3D electrode designs, we calculated a 3.5-fold larger surface area than the corresponding 2D design. The surface area of a fuel cell determines its amperage, meaning that fuel cell power is directly proportional to the electrode surface area. Smaller cells have larger surface areas relative to their volume, so they automatically feature increased power density. Microfuel cells might eventually also come at a lower cost because less material is used in their construction. Because of function integration possible in microsystems, the overall complexity may also be reduced (less peripherals), further reducing total weight and volume. Moreover, microfuel cells are expected to have a higher efficiency because of their high surface-to-volume ratio and the corresponding increase in triple points (reaction points where gas, liquid, and electrode meet) and the smaller fluidic channel sizes, which allow more efficient mass transport (for serpentine flow patterns, the flow velocity is inversely proportional to the square of the length scale). Employing microfluidic strategies, gas transport in the cell can be maximized while gas stoichiometry can be maintained and "dead zones" underneath structures minimized. Microfuel cells also may benefit from increased catalyst utilization, because microfabrication and nanostructuring techniques (see e.g., carbon nanohorns, Figure 9.8) allow for more control over catalyst deposition and distribution. Finally, it is easier to maintain a homogeneous environment within a small area, and the internal resistance is lower because of shorter conductive paths.

Example 9.1:

There have been many attempts at miniaturization of fuel cells. A recent example comes from Toshiba, which unveiled a miniature direct methanol fuel cell (DMFC) developed for small electronic devices such as digital audio players and wireless headsets (Figure 9.6). The fuel cell, measures 22 × 56 × 4.5 mm, weighs 8.5 g, and can put out 100 mW of power for as long as 20 h with a 2 cc charge of 95% methanol. The air-breathing cell has only passive components.

DMFCs are a subcategory of polymer exchange membrane fuel cells (PEMFCs) where the fuel, methanol, is not reformed but is fed directly into the fuel cell, avoiding complicated catalytic reforming steps. When a DMFC is operating, the methanol solution and oxygen gas are fed to the surface of the membrane electrode assembly (MEA) through the anode and cathode plates, respectively. Methanol is consumed at the anode catalyst layer, producing protons and electrons and releasing the byproduct CO_2. The protons directly transfer through the PEM to the cathode, while the electrons, blocked by the insulating PEM, have to travel to the cathode via the external circuit, resulting in an electrical current. The protons and electrons combine with O_2 at the cathode catalyst layer to form H_2O. Storage of methanol is easier than that of hydrogen because it does not need to be done at high pressures or low temperatures, since methanol is a liquid. Liquid methanol, as

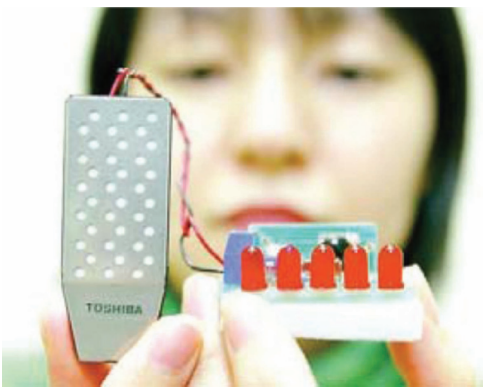

FIGURE 9.6 Toshiba's miniature direct methanol fuel cell.

the fuel of DMFC, has the advantages of easy storage and the ability to refuel instantly with no interruption of operation. The methanol cell can be directly started and operated at room temperature, which is a significant advantage for the applications of the portable electronic devices. Finally, the energy density of methanol is an order of magnitude greater than that of even highly compressed hydrogen. Methanol has an energy density of 17.6 kJ/cm^3, which is about 6 times that of a lithium battery.

Unfortunately, the efficiency of DMFCs is typically low because of the high permeation of methanol through the polymer membrane, a deleterious effect known as methanol crossover.

Fuels and Fuel Storage in Microfuel Cells

Introduction

The advent of microfuel cell-powered gadgets will require progress in the manufacture of fuel storage cartridges (see Figure 9.7).

Fuel sources for fuel cells range from highly flammable to relatively inert. Many miniaturized microfuel cells use methanol to be oxidized directly in DMFCs (see the Toshiba cell described above) or they consume hydrogen that is reformed "on demand" from methanol in reformed methanol fuel cells (RMFCs). Formic acid at a concentration of <85% by weight may be oxidized directly in a formic acid fuel cell. Liquid borohydride is either oxidized directly, in direct borohydride fuel cells (DBFCs), or reformed to hydrogen on demand, in indirect borohydride fuel cells. A butane or a butane/propane mix is oxidized directly by an SOFC system.

FIGURE 9.7 Fuel cell cartridges in consumer electronics.

Using methanol, Samsung has developed a prototype fuel cell for use in laptops that it claims lasts almost twice as long as other fuel cell systems being readied (see Figure 9.7). The Samsung fuel cell, powered by about 200 cm^3 of liquid methanol, has an energy density of 200 Wh/L. The cell measures 23 cm wide, 8.2 cm in length, and 5.3 cm deep and weighs less than 1 kg. In total, the fuel cell can supply power to a laptop for about 15 h. Such performance substantially improves over the 100–130 Wh/L energy densities of the fuel cells being developed by companies such as Toshiba (see Figure 9.6) and NEC for laptops. While hydrogen-based cells have taken off for home or automobile use, versions based on methanol for use in electronics products have yet to be commercialized. Toshiba and NEC are among the companies that promised methanol fuel cell-based laptops in previous years, but each time, technology launches have been delayed.

In what follows, we analyze in a bit more detail progress made in hydrogen storage using CNTs and carbon nanohorns and the prospect of biomass as fuels in biofuel cells.

Hydrogen Storage

The chemical energy per mass of hydrogen (142 MJ kg^{-1}) is at least three times larger than that of other chemical fuels (for example, the equivalent value for liquid hydrocarbons is 47 MJ kg^{-1}). Also, hydrogen as a fuel leads to pure water as a byproduct, and the hydrogen/oxygen reaction is a reaction for which catalysts have been researched the most. The problem of storing hydrogen safely and effectively is one of the major technological barriers currently preventing the widespread adoption of hydrogen as an energy carrier and the subsequent transition to a so-called "hydrogen economy." Practical problems with storage of hydrogen gas or liquid make solid state storage the

most attractive. To appreciate the challenge, consider that 4 kg of hydrogen gas, which is required for a practical driving distance, occupies a volume as large as 49 m^3. Storage solutions must reduce the enormous volume of the hydrogen gas. A solid medium capable of absorbing and releasing large quantities of hydrogen easily and reliably is actively being sought and various types of solids have been proposed, including microporous materials that can store physisorbed molecular hydrogen at low temperatures,[11] intermetallic hydrides that absorb atomic hydrogen as an interstitial,[12] and complex hydrides formed from light elements, such as Li, B, Na, Mg, and Al.[13,14] GE, for example, is working with the Department of Energy (DOE) on $Li_2Mg(NH)_2$, which contains 5.6% hydrogen and has reversible storage capability. As a threshold for economical hydrogen storage, the DOE has set storage requirements for the DOE Freedom CAR program at 6 weight % (wt%) to be considered for technological implementation.

Among the storage methods currently being explored, storing hydrogen by adsorption in metals appears too expensive. However, trapping it in porous materials is not only efficient (all the hydrogen adsorbed can be recovered) but cheap. What's more, the cycle of hydrogen storage and release does not require any reactivation or regeneration of the material. Accordingly, considerable research efforts are going into the evaluation of various nanostructures, such as CNTs, to find the most suitable lightweight hydrogen storage material. Because of their cylindrical and hollow geometry and nanometer-scale diameters, it was predicted that CNTs would store liquids or gases in their inner cores. Claims of storage of hydrogen in CNTs attracted worldwide interest when Dillon et al. published 5–10 wt% hydrogen storage in single-walled carbon nanotubes (SWNTs).[15] Subsequently, claims of high hydrogen storage capacities at room temperature and pressures higher than 100 bar in graphitic nanofibers (GNFs) and lithium- and potassium-doped multiwalled carbon nanotubes (MWCNTs) were made. But in the late 1990s, the identification of many erroneous measurements of gaseous hydrogen uptake by CNTs and CNFs led to a controversy that is still lingering today.*[16] In light of today's knowledge, it is not very likely that at moderate pressures and around room temperature carbon nanostructures can store the amount of hydrogen required for hydrogen-based fuel cells (at least not for fuel cells for cars): using them for storage is possible only at extremely low temperatures (below –196°C) because of the weak interaction between hydrogen and carbon. The future possibility of storing hydrogen inside carbon-based porous materials, as part of a clean energy scheme, depends on the force of the interaction between hydrogen and carbon and on how easily this force can be increased.

Another possibility for hydrogen storage is electrochemical storage in CNTs. In this case, it is not a hydrogen molecule but a hydrogen atom that is physisorbed. Currently, the storage of hydrogen in this absorbed form in carbonaceous materials is considered the most appropriate route to solve the hydrogen storage problem. While most of the studies have focused on the hydrogen storage through physisorption, recent density functional theory (DFT) calculations for single-walled CNTs indicate the potential for up to 7.5 wt% hydrogen storage capacity through chemisorption by saturating the C-C double bonds in the nanotube walls and forming C-H bonds (i.e., hydrogenation; see the articles "Generalized Chemical Reactivity of Curved Surfaces: Carbon Nanotubes"[17] and "Theoretical evaluation of hydrogen storage capacity in pure carbon nanostructures"[18]). However, direct experimental evidence of the high values of the hydrogen capacity through chemisorption has not yet been demonstrated, and so far, the only storage systems that have met the DOE targets are compressed tanks of gas and liquid. A 2004 report by the American Physical Society concluded that even the most promising solid-storage technologies are still several breakthroughs away from practical use.

* Some of the physical properties of hydrogen, including its low molar mass relative to gas phase impurities and its susceptibility to leakage and permeation, together with the sensitivity of the materials that can be used to store it, mean that hydrogen sorption measurements are particularly prone to error.

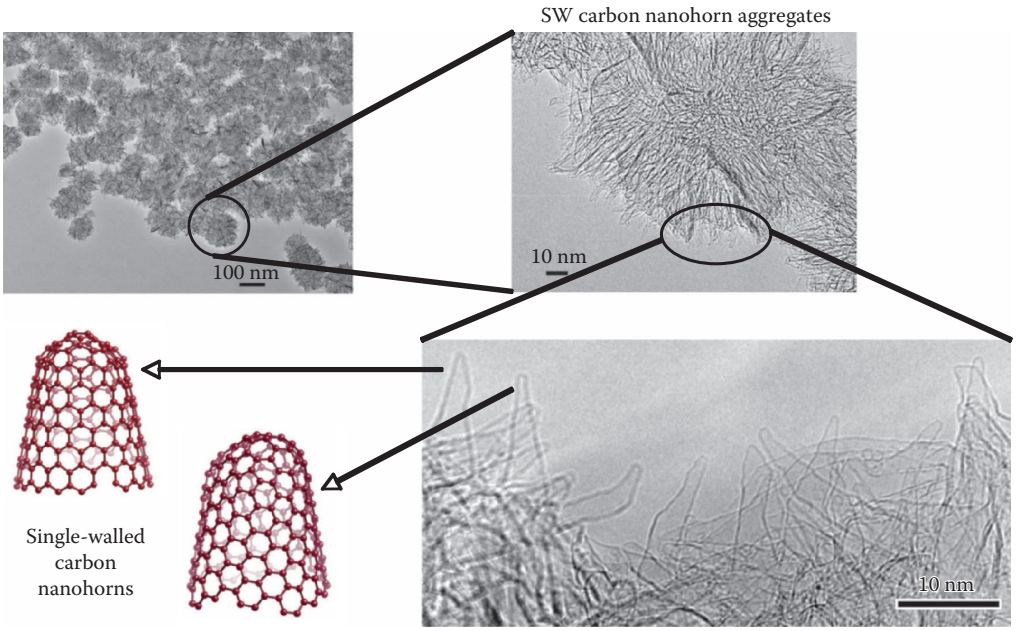

FIGURE 9.8 Carbon nanohorn aggregates and individual carbon nanohorns. (From Iijima, S., et al. 1999. *Chem Phys Lett* 309:165.[20])

Carbon nanohorns offer a better prospect for hydrogen storage in fuel cells than CNTs. Nanohorns are pure carbon structures that are 2–3 nm long, are cone-shaped, and aggregate to form dahlia-shaped structures 80–100 nm in diameter with a large number of horn-shaped, short, single-layered nanotubes that stick out in all directions (Figure 9.8). Since the tips of the cones are pointed, it was suspected that there might be a stronger hydrogen-substrate interaction than in CNTs. Recently, researchers at the Centre National de la Recherche Scientifique (CNRS) confirmed that with carbon nanohorns structures, the hydrogen-carbon interaction is indeed far more stable than with nanotubes.[19] This group demonstrated that nanohorns have remarkable adsorptive behavior because of their large surface area (about 400 m^2/g) and excellent catalytic properties because Pt catalyst is dispersed more homogeneously on the surface of carbon nanohorns. Unlike single-walled CNTs, carbon nanohorns can be made without the use of catalysts. Carbon nanohorn aggregates can be produced with a yield of more than 90% through laser vaporization of carbon at room temperature. Sumio Iijima's group showed that they could also be produced by laser ablation of graphite, and these were the researchers who came up with the name *nanohorns*.[20]

Carbon nanohorns are expected to perform excellent as gas storage material, making use of their high adsorbability.* Carbon nanohorns have actually cleared the DOE threshold for commercial adoption as methane gas storage material.

Biofuels

Not everyone agrees that improved hydrogen storage is the way to further develop microfuel cells. Some researchers point out that proponents of a hydrogen economy claim to address greenhouse gas (GHG) emissions, but in reality, these experts counterargue, the most economic methods of making hydrogen is from natural gas and these processes produce significant amounts of GHGs. Since virtually all living things in the biosphere operate by using biomass as fuel and generate power using fuel cells, these scientists propose that a biomimetic approach would appear to be the most environmentally sustainable method of producing energy. The most common energy currencies on the planet, used by virtually every living thing, are found in landfills, wastewater

* Carbon nanohorns selectively adsorb DNA fractions. Inorganic materials are mostly used today in selecting DNA fractions. However, carbon, with its excellent biocompatibility, may be a better material than inorganic substances. See http://www.nanonet.go.jp/english/mailmag/2004/023a.html.

treatment plants, wood waste, agricultural waste, grasses, etc. The mechanism of biofuel cells involves the oxidation of substrates such as carbohydrates, proteins, or fats by microorganisms or enzymes generating electrons in an external circuit. Biocatalyzed oxidation of organic substances by oxygen or other oxidizers in a two-electrode cell provides a potential means for the conversion of chemical to electrical energy, even in the body of a living subject. Like conventional fuel cells (such as methanol fuel cells), these types of cells can deliver more energy per volume weight than conventional batteries, and the theoretical efficiency of biofuel cells is estimated to be as high as 90% (compared with up to 60% for other fuel cells; see above). Abundant organic raw materials, such as amino acids or glucose, can be used as fuels in biofuel cells for the oxidation process, and molecular oxygen can act as the substrate being reduced. If the biofuel cells use concentrated sources of chemical energy, they can be made safe, small, and light. Moreover, biofuel cells differ from the traditional fuel cells by the material used to catalyze the electrochemical reaction. Instead of using precious metals as catalysts, biofuel cells rely on biological molecules, such as enzymes, to carry out the reaction.

Biofuel cells are categorized into microbial-based and enzymatic biofuel cells, which employ biocatalysts, i.e., either microorganisms or enzymes, respectively, to convert chemical energy into electrical energy. Biocatalysts are attractive compared with transition metal catalysts because 1) they operate at moderate temperatures, 2) they allow for the use of inexpensive fuel cell components, 3) they are renewable, and 4) they can be developed for a variety of cheap fuels. Enzymatic biofuel cells are preferred over microbial ones. Microbial-based biofuel cells have too many disadvantages: complex design, big size, poor reproducibility, and short lifetime based on bacterial survival.

As an example of an enzymatic biofuel cell, consider the glucose cell in Figure 9.9. Here, oxidation of glucose is coupled to the reduction of dissolved O_2. The cell incorporates an anode consisting of sugar-digesting enzymes and mediator, and a cathode comprising oxygen-reducing enzymes and mediator. The anode extracts electrons and hydrogen ions

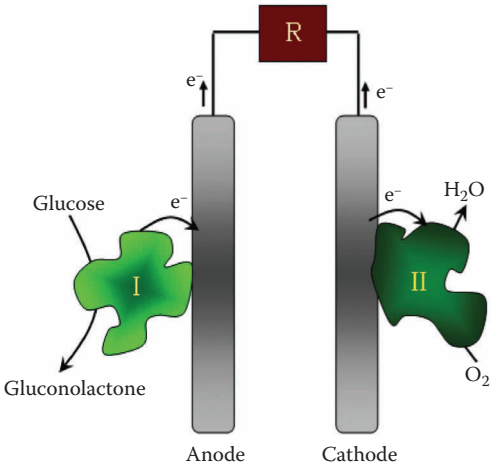

FIGURE 9.9 Biofuel cell based on glucose oxidation and oxygen reduction.

from the sugar (glucose) through enzymatic oxidation as follows.

$$\text{Glucose} \rightarrow \text{Gluconolactone} + 2\,H^+ + 2e^- \qquad \text{Reaction 9.4}$$

The hydrogen ion migrates to the cathode, and once it arrives at the cathode, the hydrogen ions and electrons absorb oxygen from the air to produce water.

$$(1/2)O_2 + 2\,H^+ + 2e^- \rightarrow H_2O \qquad \text{Reaction 9.5}$$

Through this electrochemical reaction, electrons pass through the outer circuit to generate electricity. Power output of this cell is the product of the cell voltage, V_{cell}, and the cell current, I_{cell}. The oxidation reaction may be catalyzed by glucose oxidase (I) at the anode, and oxygen reduction may be catalyzed by laccase (II) (or bilirubin oxidase) at the cathode. Since most of the redox enzymes lack direct electrical communication with electrode supports, various electron mediators have to be used to contact the biocatalyst electrically with the electrodes. A redox mediator of appropriate redox potential is required to shuttle electrons between the protein and the electrode surface, because direct electron transfer to buried redox sites within these proteins is generally not possible given the distance of the active site from the electrode surface (for more details, see Volume I, Chapter 7).

For the pictured glucose/O_2 biofuel cell, a V_{cell} higher than 0.5 V can be achieved by the utilization

of enzymes and redox mediators of carefully chosen redox potentials. The mediators and enzymes can be immobilized on the electrodes by, among others, codeposition of redox polymer/enzyme and a bifunctional linker, coelectrodeposition and enzyme reconstitution at a functionalized electrode surface to provide membrane-less biofuel cells. The immobilization concept represents an important advancement, as it precludes the need to separate the anode and cathode half-cells from each other using a membrane, provided that no solution redox reaction between fuel and oxygen occurs (as is the case for glucose). See http://www.tappi.org/content/events/10nano/papers/20.2.pdf.

Example 9.2:

Sony, one of the world's largest battery makers, has succeeded in creating a sugar-based biofuel cell. The biofuel cell does not require mixing or convection of the glucose solution or air movement; as it is a passive-type cell, it works simply by supplying sugar solution into the unit. Their test fuel cells measure 39 mm^3 and delivers 50 mW—currently the world's highest level for passive-type biofuel cells of comparable volume. The biobattery casing is made of vegetable-based plastic (polylactate) and is designed in the image of a biological cell. By connecting four cubic cells, it is possible to power a memory-type Walkman (NW-E407), together with a pair of passive-type speakers (no external power source) (see Figure 9.10).

FIGURE 9.10 Sony's biofuel cell based on glucose solutions. Four units are shown to power a Sony Walkman. (Courtesy of Sony.)

Key achievements in the development of the Sony biofuel cell include the following:

1. Enhanced immobilization of enzymes and mediator on the anode. For effective glucose digestion, the anode contains high concentration of enzymes and mediator. The Sony immobilization technology involves two polymers to attach enzyme and mediator to the anode. The polymers feature an opposite charge, so the electrostatic interaction between the two polymers effectively secures the enzymes and the mediator closely together. The ionic balance and immobilization process have been optimized for efficient electron extraction from the glucose.
2. Cathode structure for efficient oxygen absorption. The water content within the cathode environment is vital to ensure optimum conditions for the efficient enzymatic reduction of oxygen. The Sony biofuel cell employs porous carbon electrodes partitioned using a cellophane separator. The optimization of this electrode structure ensures that the appropriate water levels are maintained, enhancing the reactivity of the cathode.
3. Optimization of electrolyte. A phosphate buffer of approximately 0.1 M is generally used within enzymology research; however, an unusually high 1.0 M concentration buffer is used in the Sony biofuel cell. This is based on the discovery that such high concentration levels are effective for maintaining the activity of enzymes immobilized on the electrodes.

Sony continues its development of immobilization systems, electrode composition, and other technologies in order to further enhance power output and durability, with the aim of realizing practical applications for these biobatteries in the near future.[21, 22]

Despite the many advances in enzyme and polymer membrane modified electrode techniques, current enzymatic biofuel cells cannot compete with conventional batteries because of their low cell voltages and power densities. In addition, other key challenges of enzymatic biofuel cells include an uncertain storage and operational stability, tedious pretreatments of special and expensive

electrode materials with a subsequent complex chemical, and/or electrochemical functionalization, the adsorption of many interfering species on the electrodes, etc.

Implantable biofuel cells are proposed to convert the energy stored within chemicals present in vivo into usable electrical energy. The microbiofuel cell is potentially an ideal power source for a variety of devices that need to be implanted for short periods of time (i.e., from a few days to a period of a couple of weeks), such as medical sensor/transmitter systems and injectable biosensors, because of its easy integration with the sensor-transmitter system fabricated by MEMS technologies. Current biofuel cells cannot compete with conventional electrochemical cells in powering implantable MEMS devices, such as in situ and in vivo biosensors. Normally these cells would produce continuously a few microwatts, of which less than 1 μW l is required for the operation of the sensor; the transmitter consumes most of the power. With a small ultracapacitor storing ~10 mJ, enough for 1-ms-long 1–10 GHz bursts of 10 μW every 10 s, the transmitted information is easily acquired outside the body. Even though microwave irradiation has been used to charge these devices, if one considers the potential health risks of direct microwave irradiation, the biofuel cell could be more convenient and safe for the patients.

Micromachining of Microfuel Cells

To appreciate the many challenges involved in micromachining a fuel cell, let us start by considering how one is typically constructed (see Figure 9.11). To focus the mind we assume that we are dealing with miniaturization of a passive PEM fuel cell. In general, passive-type fuel systems have a more simple structure and are more suitable for miniaturization, whereas active type systems have a more complicated structure and are suited to higher power devices. A PEMFC contains an electrolyte that is a layer of solid polymer that allows protons to be transmitted from one face to the other. PEMFCs require hydrogen and oxygen (or air) as inputs, and these gases must be humidified in most cases. The operating temperatures are relatively low, at around 60–80°C.

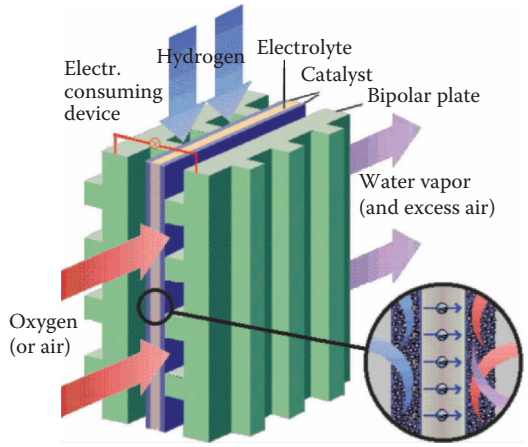

FIGURE 9.11 Construction of a typical fuel cell.

Figure 9.11 shows one fuel cell element only and these elements can be either stacked (Figure 9.12a) or put in an array. A fuel cell array can either be banded or flip-flopped as illustrated in Figure 9.12b.

Bipolar plates have a structural, an electrical, and a fluidic function. The requirements for the bipolar plates in the microfuel cells pictured in Figure 9.11 include high electrical conductivity, resistance to corrosion, chemical compatibility, high thermal conductivity, low leakage of gases, high mechanical robustness, low weight, manufacturability, and low cost. Graphite satisfies all these criteria except for mechanical robustness, manufacturability, and low cost. Bipolar plates are a significant part of the PEMFC stack and account for 80% of the total

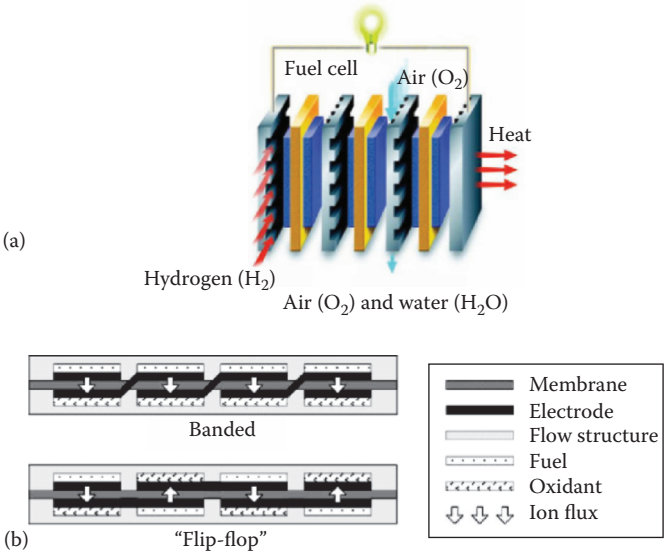

FIGURE 9.12 (a) Fuel cell stack. (b) Two methods for arraying fuel cell elements.

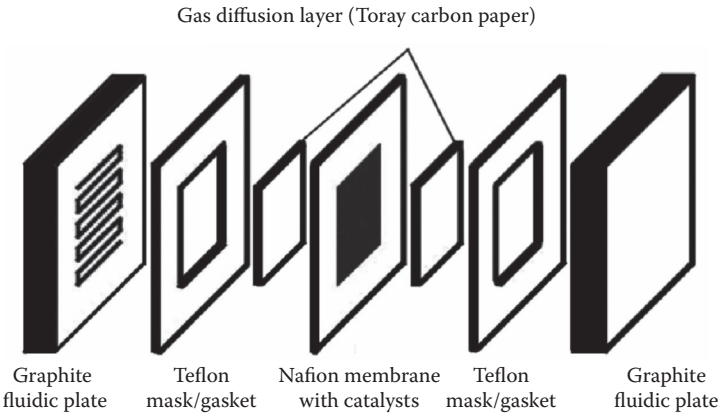

FIGURE 9.13 Bipolar plates (also called graphite fluidic plates) and typical membrane electrode assembly (MEA).

weight and 45% of stack cost. The bipolar plates will obviously be an important first target in miniaturizing a fuel cell. The membrane electrode assembly (MEA) in a PEMFC, illustrated in Figure 9.13, may consist of a Nafion® membrane (Nafion 112, Electrochem, Woburn, MA) coated with catalyst sandwiched between two carbon paper layers (e.g., Toray carbon paper). The carbon papers act as gas diffusion layers, and they are pushed up against the Nafion membrane using two Teflon gaskets.

A wide variety of micromachining techniques have been employed to construct microfuel cells, including Si MEMS-based, printed circuit (PC)-board-based, and carbon MEMS-based. An example of a Si-based MEMS-based fuel cell is shown in Figure 9.14.[23]

In this Si design, electropolished tubs in the highly conductive Si bipolar plates make for gas flow channels. Nafion is used as the membrane, and porous Si plays the role of gas diffusion layer to bring the gas to the Pt/C electrodes on the Nafion surface. Other Si MEMS-based fuel cells are reviewed in Table 9.4.

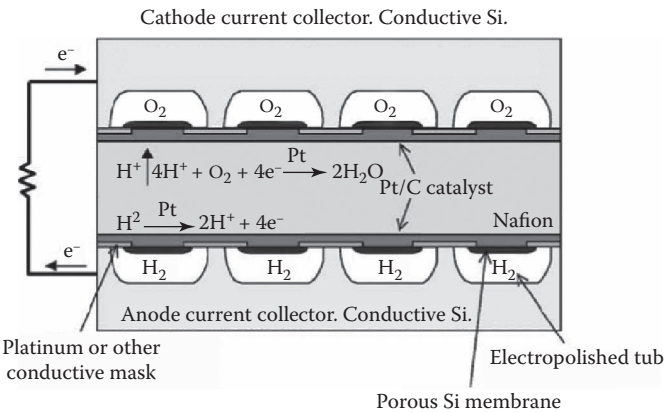

FIGURE 9.14 Silicon-MEMS-based fuel cell.[23]

Silicon is expensive compared with the printed circuit board-based fuel cell depicted in Figure 9.15.

Dr. Ben Park made the world's smallest hydrogen-air fuel cell with carbon-MEMS bipolar plates while working in the author's laboratory.[24] C-MEMS describes a manufacturing technique in which carbon devices are made by exposing a prepatterned organic structure to high temperatures in an inert or reducing environment (i.e., pyrolysis). The C-MEMS process makes the fabrication of intricate carbon shapes as easy as the patterning/machining/molding of a selected polymer material (see Chapter 5 for details).

For the manufacture of C-MEMS bipolar plates, 20-mil (~500-μm)-thick Cirlex® (Fralock, Canoga Park, CA) plastic sheets were machined using a circuit board milling tool (T-Tech, Norcross, GA) with 500-μm diameter end mills to create the fluidics. When starting with a size of the polymer bipolar plates of 1 × 1 cm, shrinkage during the pyrolysis process reduces the plates to 0.8 × 0.8 cm (see Figure 9.16).

For the membrane electrode assembly (MEA), commercial fuel cell electrodes [1 mg/cm^2 loading, 20 wt% Pt/Vulcan XC-72 (EC-20-10-7; Electrochem-Woburn, MA)] are pressed into an activated Nafion membrane* (Nafion 115) (Figure 9.17).

The fluidic channel walls and separators machined from high-temperature polymer sheets are bonded together (using PI-5878G polyimide) to create

* The Nafion membrane is activated as follows: deionized (DI) water for 1 h, 30% H_2O_2 for 1 h, 10 M H_2SO_4 for 1 h, and finally a short rinse in DI water (all at 80°C). The Nafion is stored in DI water until fabrication of the MEA.

fluidic plates as shown in Figure 9.18. The polymide physical binder also acts as the electrical binder when converted to carbon during pyrolysis. The MEA, fluidic plates, and gas inlet/outlets (cut from conventional syringes; see Figure 9.19b) are brought together, and epoxy is used to seal the entire fuel cell structure.

Making bipolar plates by C-MEMS technology has several benefits. Because one starts from an easy-to-machine polymer, new types of bipolar plates become feasible, and because the bipolar plate fluidics, gas diffusion layer, and catalyst support layer are all made of carbon, they can be integrated and fabricated into a single monolithic structure. This reduces weight, size, complexity, and internal resistance while increasing mechanical robustness. Control over the carbon precursor material allows materials engineering of the carbon itself.

The open-circuit voltage of an individual unoptimized C-MEMS cell has been measured at 871 mV, and the closed-circuit current draw of the fuel cell stabilized at 3.11 mA (with a voltage of 110 mV). The maximum power output was 0.773 mW (1.21 mW/cm^2), with an internal resistance of about 210 Ω.[24]

Our team also successfully fabricated a hydrogen-air C-MEMS fuel cell stack, as depicted in Figure 9.19.[24] The gaskets between cell elements are made of silicon rubber, which provides elastic support of the repeating parts and prevents leakage of gases. The end plates are machined in a T-Tech circuit board milling tool to create the screw holes and openings for gas ports. The latter are cut from conventional syringes. Repeating the bipolar plates, the gaskets, and the MEAs and then compressing them with four screws in the four corners of the whole structure results in the completed fuel cell stack, as shown in Figure 9.19.

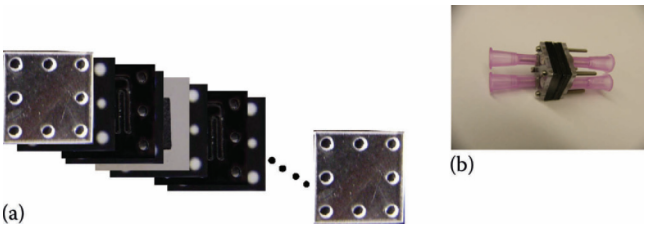

FIGURE 9.19 Hydrogen-air carbon-MEMS fuel cell stack. (a) The MEA, fluidic plates, and gas inlet/outlets (cut from conventional syringes) are brought together, and epoxy is used to seal the entire fuel cell structure (b).

The C-MEMS fuel cell could be further improved by engineering the carbon electrodes further. This may involve at least three strategies: incorporation of SWNTs and/or multiwall carbon nanotubes (MWNTs), the use of carbon horns, and the use of carbon fractals. Compared with other forms of carbon electrodes (such as graphite and bare glassy carbon electrode), MWNT microelectrodes show better performances because of the dimensions of the MWNTs and their electronic structure.[24] As we pointed out above, fuel cell electrodes, made of carbon nanohorns are expected to help improve the cells' power-generation capacity even further and extend their lifetime, because platinum catalyst nanoparticles disperse better among carbon nanohorns and do not aggregate.[24] The concept of implementing carbon fractal electrodes for both batteries and fuel cells is introduced below (see "Fractals and Fractal Dimensions").

Finally, in the microbiofuel cell context, we briefly highlight hybrid insect-MEMS (HI-MEMS; also called *cyborg bugs*, or *cybugs*), a concept sponsored by the Defense Advanced Research Projects Agency (DARPA). The MEMS on the insect are coupled to the insect anatomy and nervous system and draw power from the insect to control its locomotion by obtaining motion trajectories either from global positioning system (GPS) coordinates or by using radiofrequency (RF)-, optical-, or ultrasonic-based remote control. DARPA has military applications in mind for HI-MEMS, with visions of insect swarms with various embedded MEMS sensors (such as cameras, microphones, and chemical sniffers) penetrating enemy territory (e.g., the Crawford Ranch). The HI-MEMS battalions would perform reconnaissance missions beyond the capabilities of soldiers. But robo-insects, equipped with chemical sensors, might also have civil applications, perhaps to explore a hazardous chemical spill zone and report back about it to humans in a

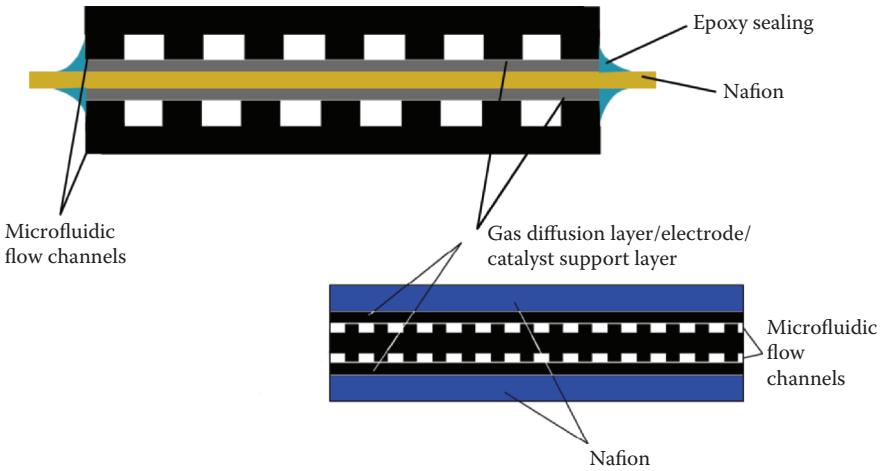

FIGURE 9.18 Assembly of carbon-MEMS fuel cell.

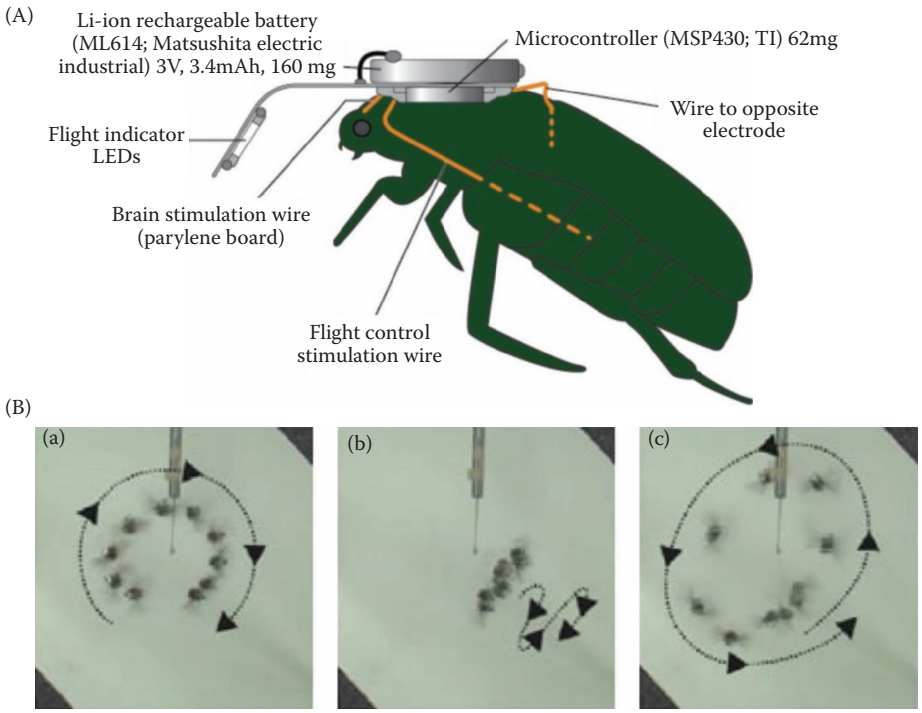

FIGURE 9.20 (A) Cyborg beetle system. The microcontroller controls flight by stimulating brain, wing, and other nerves. An array of ten light-emitting diodes hanging in front of the beetle's eyes is lit to control flight without direct nerve stimulation. The beetle weighs 1–2 g, and the total control system weighs 422 mg. (From Nikkei Electronics Asia, April 2008.) (B) Electrical stimulation of wing muscles on either side initiates a turn. Beetles mounted on a long string (10 cm) were programmed with a continuous sequence of left, pause, right, pause instructions; each instruction lasted 2 s. Left flight muscle stimulation generates a right turn (a), followed by a pause during which the beetle zigs and zags (b), followed by right muscle stimulation that generates a left turn (c). Each photograph consists of ten frames; frames were taken every 0.2 s. (From MEMS 2008, an international academic conference on MEMS that took place January 13–17, 2008, in Tucson, AZ.)

safe zone. A recent embodiment of the HI-MEMS concept comes from a University of Michigan team that successfully created a cyborg unicorn beetle microsystem (Figure 9.20A).[25] The University of Michigan researchers equipped a North American unicorn beetle with an IC, button battery, and a flight direction indicator consisting of ten light-emitting diodes (LEDs) and succeeded in controlling its flight externally. Flight control is handled by inserting electrodes into a portion of the brain immediately behind the beetle's eye and into wing muscles, and injecting AC pulses. The LED directional controller constitutes an independent control system and utilizes the beetle's proclivity to follow a blinking light. The cyborg beetle is able to take off and land, turn left or right, and demonstrate a number of other flight control behaviors. Electrical stimulation of wing muscles on either side initiates a turn (Figure 9.20B).

The DARPA program director, Dr. Amit Lal, got the idea for remote-controlled insects from the 1990 science fiction novel *Sparrowhawk* by Thomas A. Easton. In that novel, Easton writes about genetically engineered animals that are greatly enlarged and then outfitted with implanted control structures.

Heat Engines in MEMS

A heat engine converts heat to mechanical energy. Examples of everyday heat engines include the steam engine, the diesel engine, and the gasoline (petrol) engine in an automobile. Heat engines are divided into two groups: external-combustion engines and internal-combustion engines. External-combustion engines produce hot gases that transfer heat to another fluid, and the energy in this fluid, in turn, is changed into mechanical energy. External-combustion engines include gas and steam turbines and reciprocating steam engines. Internal-combustion engines produce hot gases whose heat energy is changed directly into mechanical energy.

Several groups involved in power MEMS are investigating scaled-down versions of well-established macroscale combustion devices. The idea is that since batteries have low specific energy, and liquid hydrocarbon fuels have a very high specific energy, a miniaturized power generating device, even with a relatively inefficient conversion of hydrocarbon fuels to power would result in increased lifetime and/or reduced weight of an electronic or mechanical system that currently requires batteries for power. A gas turbine powering a generator, for example, could in principle pack thirty times the energy of any battery. Refueling would replace recharging. There are quite a few difficulties with this approach, though, one being that flames extinguish because of heat losses if the dimensions of the combustion chamber are too small. Furthermore, even if flame quenching does not occur, heat and friction losses become increasingly important at smaller scales, since the heat release due to combustion and thus power output scales with the volume of the engine, whereas the heat and friction losses scale with the surface area.

As an example application of microcombustion engines, consider satellite missions that deal with smaller and smaller satellites, so that launch systems and altitude control thrusters of reduced mass and volume are now needed. Thrusters are devices in which propellant is burnt or disintegrates to produce a controlled force in a selected direction. These small rocket engines are expected to produce thrust of the order of tens of newtons at a thrust-to-weight of over 1000, i.e., 10 times the thrust-to-weight of conventional chemical liquid bipropellant engines. A simple MEMS thruster fabricated of a silicon/glass structure is shown in Figure 9.21.[26]

The nozzle, plenum, chamber, and injector of this MEMS thruster are all etched in silicon, and a glass ceiling is bonded to the etched silicon part. Propellants that have been used in this structure include H_2O_2 and N_2H_4 with silver and platinum on Al_2O_3 as catalysts. Hydrogen peroxide is fed through the plenum and injector and reacts in the presence of the catalyst to produce heat and gases in the chamber. The gases expand through the nozzle to produce thrust.

Another postage-stamp-size microthruster, fabricated at Massachusetts Institute of Technology (MIT), was made of six layers of silicon fused together

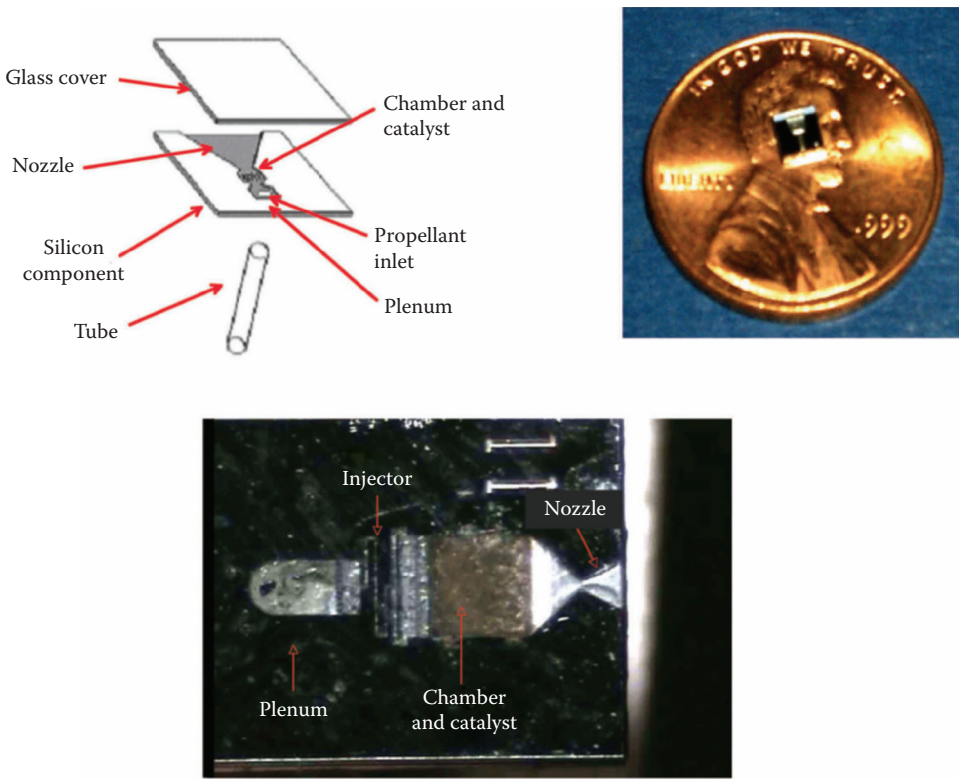

FIGURE 9.21 Simple silicon/glass thruster structure. (From a talk by Apurva Varia, NASA Goddard Thermal Model of MEMS Thruster.)

to make a sandwich 3 mm thick and was projected to produce up to 15 N of thrust by burning oxygen and methane. To prevent melting, ethanol coolant circulates around the tiny flat thrust chamber. The thrust level from these micromachined devices is expected to be very high in relation to their mass. MIT's Adam London thinks that a two-stage, 80-kg rocket might be sufficient to put a Coke-can-sized payload in orbit using 800 of his Si thrusters.[27] A more recent MIT microrocket engine thrust chamber and nozzle design measures $18 \times 14 \times 3$ mm and builds on London's earlier gaseous propellant work, expanding the operating envelope of these motors to higher thrust levels.[28] Directions for improved specific impulse engines include increasing the engine size by a factor of 2–4 and research on hydrogen peroxide as a coolant. Another approach is to use liquid hydrocarbons or solid propellants. With the combustor working at 1500–1600 K, Si with a melting point of 1685 K is out as a building material. SiC and perhaps quartz are alternative candidate materials.

MEMS thruster arrays for satellites offer several advantages over conventional thrusters: they have no moving parts; utilize a variety of propellants; are scalable; eliminate the need for tanks, fuel lines, and valves; and fully integrate the structure of the satellite with the propulsion to power it. The Honeywell-Princeton MEMS Megapixel Microthruster Array (MMMA) consists of a 256 × 256 array of pixels, each one capable of being fired as a separate thruster (Figure 9.22). The thruster operates by first igniting a small amount of lead styphanate, which in turn ignites the main propellant of a nitrocellulose mixture. This is then exhausted from the fired pixel out a channel to produce thrust. Thrusters in this class give very small and precise impulse bits (on the order of tens of mN-s). Another microthruster array, developed by TRW, Caltech, and the Aerospace Corp., is fabricated as a three-layer silicon and glass sandwich, with the middle layer consisting of multiple small propellant cells sealed with a rupturable diaphragm on one side and an ignitor on the other. Each cell is a separate thruster, and when ignited, delivers one impulse bit. Delivering propulsion in discrete increments by igniting thrusters in controlled sequences has lent the technology the name "digital propulsion."

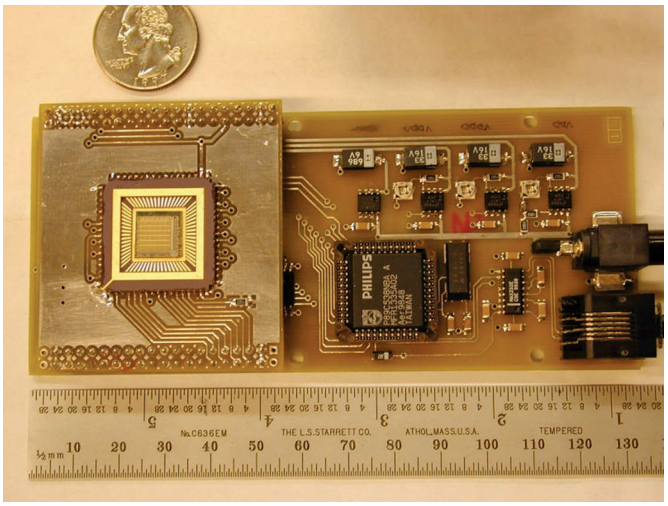

FIGURE 9.22 The MEMS Megapixel Microthruster Array ignitor thruster with its firing control board (http://alfven.princeton.edu/projects/MEMS1.htm).

The MEMS thrusters discussed above are all internal-combustion devices. External-combustion MEMS devices, with power generation by the alternate heating and cooling of a working fluid or a solid (e.g., shape memory alloys) integrated on a chip, have been attempted for driving a load as well. The heating in such an engine results typically from passing a current through a resistor. It would be preferable to use infrared radiation instead, since in that case no leads need to connect to the chip. It has been projected that a gas-based external heat engine of $5 \times 5 \times 5$ mm^3 might provide an output of 10–100 W/kg. With actuators based on shape memory alloys, an output of up to 1 kW/kg is feasible, with an efficiency ten times lower.[6] Problems associated with crafting MEMS external heat engines include the thermal isolation of heating and cooling sections, minimization of friction, and the difficulty of implementing a flywheel. Some of these problems were successfully addressed by Sniegowski and coworkers,[29,30] who demonstrated a surface micromachined microengine capable of delivering torque to a micromechanism. Angular velocities of 600,000 rpm were registered for this engine, driven by steam.

Solar Cells

Introduction

The conversion of light (photons) to electricity (voltage) in a solar cell is called the *photovoltaic* (PV)

effect. The most iconic form of solar power, the solar cell, consumes no fuel, has a wide power-handling capacity, has a high power-to-weight ratio, produces no pollution, and is more and more often made from inexpensive polycrystalline or amorphous materials, with even polymer-based solar cells being introduced. The operating principle of a solar cell was covered in Volume I, Chapter 4 (Figure 4.42), and in Table 9.5 we present a short historical overview of some important solar cell related milestones since the original observation of the photoeffect by Antoine Becquerel in 1839. As with batteries, progress in improving solar cell efficiency has been rather slow (there is no Moore's law curve for solar cells, either). Several important measures are used to characterize solar cells, the most obvious one being the total amount of electrical power produced for a given amount of solar power input. Expressed as a percentage, this is known as the solar conversion efficiency. Electrical power is the product of current and voltage, so the maximum values for these measurements are important as well: J_{sc} (short circuit current) and V_{oc} (open circuit voltage), respectively. Finally, in order to understand the underlying physics, the *quantum efficiency* is used to compare the chance that one photon (of a particular energy) will create one electron. A solar cell must be capable of producing electricity for at least twenty years without a significant decrease in efficiency, so lifespan is another crucial characteristic.

Table 9.5 Milestones in Solar Cell Development

1839: Discovery of photovoltaic effect between two electrodes in a liquid (Antoine Cesar Becquerel)
1876: Photovoltaic effect in Se (Heinrich Hertz)
1883: First solar electric module (Charles Fritts)
1906: Pochettino studies the photoconductivity of anthracene
1930: Research on Cu_2O/Cu solar cell
1941: Patent on Si solar cell (R. Ohl in Bell Labs)
1954: Crystalline Si solar cell (Bell Labs); 4% efficiency
1958: Solar panels as backup and power assist in space (*Vanguard 1*); 5 mW
1970: Zhores Alferov and his team in the USSR created the first GaAs heterostructure solar cells
1973: Oil crisis—solar energy is hot, subsequent Republican United States president kills Carter's efforts in favor of oil
1980: Solar cell using CdTe, $CuInSe_2$,TiO_2, etc.
1991: Liquid-junction solar cells with photosensitized anode invented by Michael Grätzel and Brian O'Regan at the École Polytechnique Fédérale de Lausanne, known as Grätzel cells
1995: Yu and Hall make the first bulk polymer/polymer heterojunction photovoltaic cell
2000: Peters/van Hall used oligomer-C_{60} diads/triads as the active material in photovoltaic cells (see Figure 3.15, for an example coming from the Stoddard-Zinc group)
2001: Schmidt-Mende made a self-organized liquid crystalline solar cell of hexabenzocoronene and perylene

Because of the soaring oil prices, solar energy is a hot topic again, as it was under President Carter (even Republicans now concede that cheap oil is not a US birthright). The photovoltaic cell is currently the fastest-growing form of alternative energy, increasing by 50% a year, and where a kWh of PV electricity cost 50 cents in 1995, it fell to 20 cents in 2005. BBC Research, which charts technology markets, expects the global solar market to grow to $32 billion by 2012, with thin-film solar cells expanding 45% a year.

At the earth's surface, the average solar energy is $\sim 4 \times 10^{24}$ J per year, and the 2001 global energy use was $\sim 4 \times 10^{20}$ J per year (increasing ~2% annually). In the United States alone, the average power requirement is 3.3 TW. With a 10% efficient solar cell, this means that we would need 1.7% of the land area of the United States devoted to PV to quench this thirst; this roughly corresponds to the area occupied by the interstate highways.

As we saw in Volume I, Chapter 4, a traditional semiconductor solar cell is made from an n-type and a p-type semiconductor put in contact with each other. The result is a region at the interface, the p-n junction, where charge carriers are depleted and/or accumulated on each side of the interface. The transfer of charge carriers produces a potential barrier, typically 0.6–0.7 V high. In the case of silicon (bandgap = 1.1 eV), sunlight provides enough energy to promote electrons out of the valence band into the conduction band, and when a load is placed across the cell, these electrons flow from the p-type to the n-type material, move through the external circuit, and then stream back into the p-type material, where they recombine with the valence-band holes they left behind. How sunlight creates an

electrical current in a solar cell is detailed a bit further in Figure 9.23.

If the incoming photon energy $E_\gamma < E_g$, then the photon is not absorbed; with $E_\gamma > E_g$, the photon is absorbed and the energy $E_\gamma - E_g$ is lost via thermalization. Additional losses occur through radiative recombination, trap states, and Auger recombination. If the carrier lifetime is less than the recombination lifetime then the charge is swept away by the inbuilt electric field (E). This depends on carrier mobility, defect density, carrier diffusion length, and exciton energy.

The conventional approach to PVs, as sketched in Figure 9.23, comes with several disadvantages. First, the semiconductor bandgap dictates that only photons with the bandgap energy or more contribute to producing a current. Higher-energy photons, at the blue end of the spectrum, have more than enough energy to cross the bandgap, but much of it is wasted as heat.

A cascade or tandem cell can achieve a higher total conversion efficiency by capturing a larger portion of the solar spectrum. In a typical multijunction cell, individual cells with different bandgaps are stacked on top of one another. The cells are stacked in such a way that sunlight falls first on the material having the largest bandgap. Photons not absorbed in the first cell are transmitted to the second cell, which then absorbs the higher-energy portion of the remaining solar radiation while

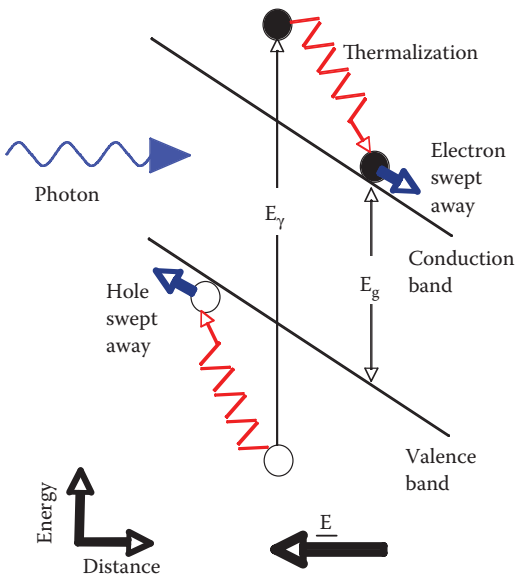

FIGURE 9.23 Energy diagram of a solar cell.

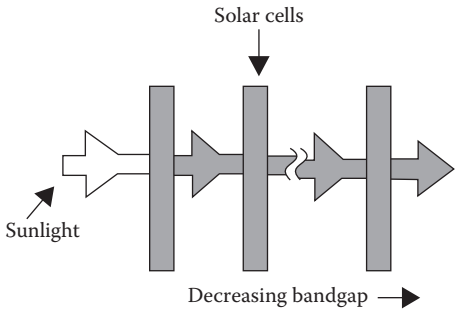

FIGURE 9.24 Multijunction, cascade, or tandem solar cell.

remaining transparent to the lower-energy photons. These selective absorption processes continue through to the final cell, which has the smallest bandgap (Figure 9.24). The ideal bandgap combination for a tandem solar cell is typically 1.75 and 1.1 eV. Such bandgap combinations can be attained using lattice-matched III–V semiconductor material combinations. The best monolithic combination is represented by the GaInP/GaAs tandem cell, possessing an AM 0 efficiency of 26.9%. The ideal efficiency for an infinite stack is 86.8%, and for a GaInP/GaAs/Ge triple-junction cell an efficiency of 32% has been measured.

Multijunction solar cells dramatically improve efficiency, but these cells are still very high-cost and suitable only for large commercial deployments (combinations include GaAs/InGaP, Ge/InGaAsN, InP/InAlAs, InP/InGaAs, and GaN/InGaN). In general terms, the types of cells suitable for rooftop deployment have not changed significantly in efficiency, although costs have dropped somewhat because of increased supply.

A higher light intensity can be focused on the solar cells by the use of mirror and lens systems, perhaps even a system that tracks the sun. This is perhaps too expensive a solution for rooftop implementation but could be useful in MEMS devices.

Another problem associated with conventional solar cells is that in order to capture enough photons in the p-type layer, that part has to be quite "thick." However, a thick p-type layer also increases the chance that electrons and holes will recombine before reaching the p-n junction. These effects combine to produce an upper limit of about 20% on the efficiency of silicon solar cells. The current problem with solar cells is not really the efficiency (20%), but rather the cost of production. Though it has come

down by a factor of 100 in fifty years, it still has to go down by a factor of 2–5 to be competitive with fossil plants.

The best known solar cells today remain based on Si, and they are either monocrystalline, polycrystalline, or hydrogenated amorphous (α-Si:H) based. Polycrystalline films are poured and are cheaper and simpler to make than monocrystalline silicon that is Czochralski grown (see Volume I, Chapter 4). The efficiency of polycrystalline cells is, however, somewhat less than that of monocrystalline cells. Hydrogenated amorphous Si (α-Si:H) cells are relatively cheap, but they come with the lowest efficiency (see Table 9.6). Although its semiconducting properties are inferior to those of single-crystal Si, we learned in Chapter 5 that α-Si:H, manufactured by plasma-enhanced chemical vapor deposition (PECVD) from silane, can be doped both n- and p-type (in contrast to α-Si) (see Table 5.8 for state-of-the-art parameters of PECVD α-Si:H). Exposure of α-Si:H to light increases photoconductivity by four to six orders of magnitude, and the absorption coefficient of α-Si:H is more than an order of magnitude larger than that of single-crystal Si near the maximum solar photon energy region of 500 nm. Accordingly, the optimum thickness of the active layer in an α-Si:H solar cell can measure 1 μm, much smaller than that of single-crystal Si solar cells. In Figure 5.15, we compared polycrystalline-based solar cells with ultrathin amorphous Si on glass and ultrathin amorphous Si on flexible substrates.

Solar cell technology represents the most MEMS-compatible technology for power integration. Lee et al.[31] note that hydrogenated amorphous silicon solar cells are a particularly attractive means to realize an onboard MEMS power supply, and they implemented a high-voltage integrated solar cell array[31] as an electrostatic MEMS power supply. By interconnecting 100 individual solar cells in series, this team measured an open circuit potential as high as 150 V under AM 1.5 conditions, a voltage high enough to drive onboard electrostatic actuators. The conversion efficiency in that effort was only 0.2%, however. Sakakibara et al.[32] were able to generate more than 200 V with a similar solar cell on an area of 1 cm^2 and obtained a conversion efficiency of 4.65%. In both cases, amorphous silicon was used in a triple-stacked PV structure generating up to 2.3 V per cell. To obtain a very dense packing of array elements and to make the series connection of the solar cells, the latter group used focused laser beams for patterning electrodes and PV materials.

Since solar light is only intermittently available, electric storage elements need to be implemented as well. Along this line, Kimura et al.[33] fabricated a miniature optoelectric transformer consisting of a p-n junction photocell and a multilayer spiral coil transformer.

III/V solar cells are cells with a high efficiency, but they are made of very expensive semiconducting materials. A single junction cell based on GaAs comes with an efficiency of 25.1%. In 1970, Zhores Alferov and his team in the USSR created the first GaAs heterostructure solar cells. Today, the combination of GaAs with germanium and indium gallium phosphide is the basis of a triple-junction solar cell that holds the record for solar light conversion efficiency of over 32% and can operate also with light as concentrated as 2000 Suns.* This type of solar cell powers the robots *Spirit* and *Opportunity*, which are exploring the surface of Mars.

Newer solar cell materials include thin films of copper indium diselenide ($CuInSe_2$), copper indium gallium diselenide (CIGS), and cadmium telluride (CdTe). Commercial leaders in this area are a firm called First Solar, which uses cadmium telluride, and Miasolé, which manufactures a thin-film PV cell based on an ultrathin layer of photoactive CIGS on a stainless steel foil only 50 μm thick. The latter can easily be used in PV modules or incorporated into building materials such as membrane roofing. The efficiencies and bandgaps of GaAs and two of

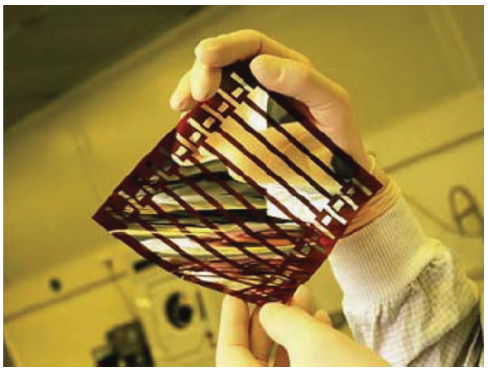

FIGURE 9.26 Polymer or organic photovoltaics.

the newer solar materials are compared with those of single-crystal and amorphous Si in Figure 9.25.

One development that made organic PVs an attractive option is the availability of light-sensitive conjugated polymers: polymers with alternating single and double carbon-carbon (sometimes carbon-nitrogen) bonds. In the 1970s, it was discovered that chemical doping of conjugated polymers increased electronic conductivity several orders of magnitude. Since that time, electronically conducting materials based on conjugated polymers have found many applications, including sensors, LEDs, and solar cells. Advantages of polymer or organic PVs (OPVs) include the fact that they are easily processed over large areas using spin-coating, doctor blade techniques (wet-processing), evaporation through a mask (dry processing), and printing (Figure 9.26). The usage of roll-to-roll printing, especially, guarantees a favorable cost (see Figure 1.5). They also have a low weight, exhibit mechanical flexibility and transparency, and have a bandgap that can easily be tuned chemically by incorporation of different functional groups. Efficiencies stand at 5%, but there are no obstacles identified for 10%. The low cost of plastic PV may enable solar power in applications where it was previously uneconomic (e.g., solar tents, sails, packaging, etc.). For rigid cells, ITO (Indium tin oxide)-coated glass usually serves as the substrate for these organic cells.

Figure 9.27 summarizes the best research solar cell efficiencies for a broad range of materials from universities, research institutes, and private companies. Besides PV converters for solar light and laser

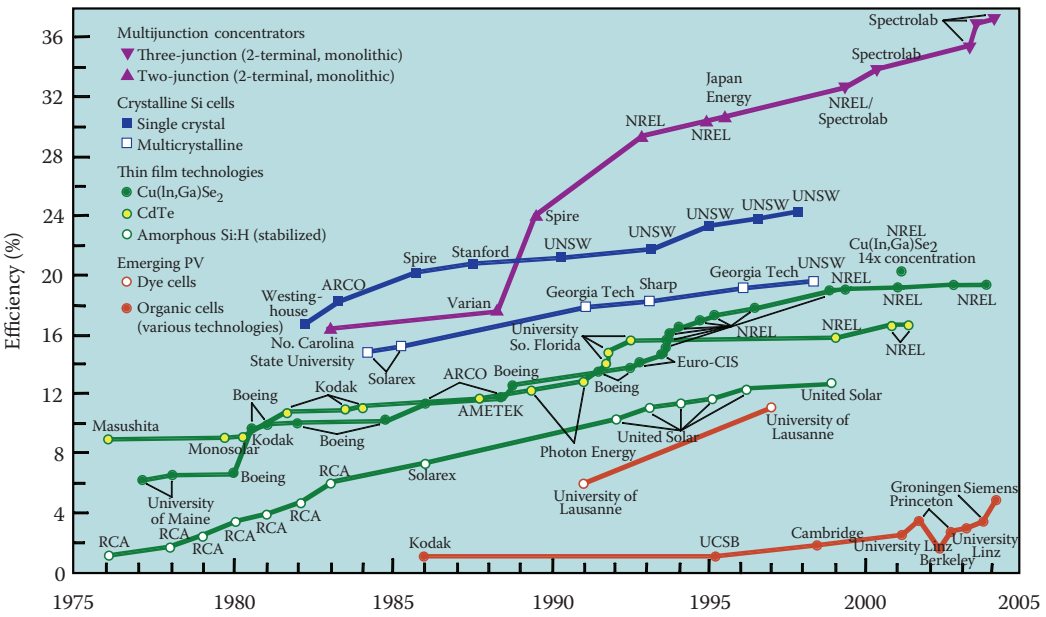

FIGURE 9.27 Research solar cell efficiencies. (From Art Nozik, DOE Solar Energy Workshop, 2005.)

light, microwaves could be used to power microsystems. In the latter, extremely small receivers and converters need to be constructed.

MEMS and NEMS in Solar Cells

Introduction

Micro- and nanotechnologies are crucial to increasing the efficiency of existing solar cells, and NEMS is enabling totally new solar cell designs as well. MEMS techniques allow for the fabrication of lenses (including Fresnel lenses), mirrors, photonic crystals, and cavities and the texturing of solar cell surfaces to enhance the interaction of incoming photons with the solar cell active junctions. As an example of a nanoenhancement of existing solar cells, consider the use of quantum dots (QDs) to replace dyes in luminescent concentrators.

NEMS may make a much bigger impact, though, on future solar cells. QDs, for example, exhibit optical properties that are absent in the bulk material due to the confinement of electron-hole pairs, in a region of a few nanometers and the wavelength at which a QD absorbs or emits radiation can be adjusted at will (see Volume I, Chapters 3 and 5). A first advantage of QDs, then, stems from the fact that an optimum bandgap, corresponding to the highest possible solar-electric energy conversion, can be achieved by using a mixture of QDs of different sizes for harvesting the maximum amount of the incident light (E_γ). A second advantage stems from the increased possibility of multiphoton absorption by nanoparticles. The formation of multiple excitons per absorbed photon takes place only when the energy of the absorbed photon is far greater than the semiconductor bandgap (E_g). Multiple photon absorption does not readily occur in bulk semiconductors, where the excess energy quickly dissipates as heat before it can create other electron-hole pairs. However, in semiconducting QDs, the rate of energy dissipation is reduced dramatically, and with the charge carriers confined within a nanovolume, their interactions are enhanced, increasing the probability for multiple excitons per incoming photon. A third advantage of QDs is that in contrast to traditional crystalline semiconductor materials that are rigid, QDs can be molded into a variety of different forms, such as sheets or three-dimensional arrays. Quantum dots can easily be combined with organic polymers or dyes or made into porous films, and in colloidal form, they can be processed to create junctions on inexpensive substrates such as plastics or thin metal foils. A fourth advantage of QDs is that it is quite easy to decouple the absorption and charge separation process. Decoupling charge separation from light absorption results in many more engineering options to make the solar cell of the future. For example, the charge separation may be achieved in a semiconductor QD, while the light absorption may be in an organic dye adsorbed on its surface.

The broader quantum solar cell strategy is thus to sensitize a first material with bandgap E_g with another material of bandgap (E_q) smaller than E_g (i.e., $E_q < E_\gamma < E_g$), and this second semiconductor material can be a dye (monomeric), a photoactive biopolymer, a QD, or a quantum well. QDs have the advantage over dyes as they degrade less in sunlight. In its simplest form, a quantum well solar cell (QWSC) consists of a p-i-n solar cell with a multiple quantum well (MQW) system added to the intrinsic (i) region. The idea, as with a tandem solar cell, is that the quantum wells absorb light of energy below the bulk bandgap, E_g.

MEMS in Solar Cells

MEMS techniques allow for the fabrication of lenses (including Fresnel lenses), mirrors, photonic crystals, cavities, and solar cell surface textures to enhance the interaction of incoming photons with the solar cell. A simple method to put MEMS to work in a conventional solar cell is by surface structuring the cell so that the light hits the PV several times, as illustrated in the pyramid structuring in Figure 9.28.[34]

NEMS in Solar Cells

We present examples of quantum technology benefiting solar cells by highlighting nanoporous semiconductors in the liquid-junction Grätzel solar cell, two-photon excitation in hybrid organic-QD PV devices, and increased efficiency in a QWSCs.

In Volume I, Chapter 7, we learned that in liquid-junction solar cells, to avoid corrosion of the cell, one chooses a redox system where the maximum density

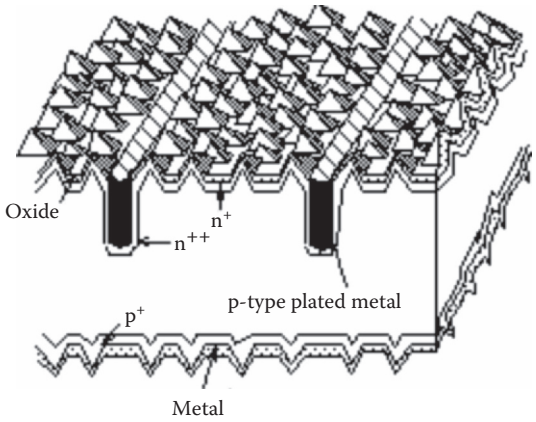

FIGURE 9.28 Surface structuring of a solar cell surface.[34]

of states of the reductant (the peak of the Gaussian in Volume I, Figure 7.62) is at the same level as the valence band edge of the semiconductor.[35] In this configuration, empty levels (holes) in the valence band, generated by shining light on the electrolyte/semiconductor interface, react with the reductant rather than with the semiconductor itself. In such liquid-junction solar cells, appropriate reductants thus compete effectively with the oxidation/corrosion of the semiconductor because they react more avidly with the holes in the valence band than the material itself.[36] The maximum voltage generated by such a cell, in theory, is simply the difference between the Fermi level of the semiconductor and the redox potential of the electrolyte.

The best known liquid-junction solar cell today is the dye-sensitized Grätzel design.[37–39] The Grätzel cell is significantly different from a conventional semiconductor solar cell, in which the semiconductor acts as the source of photoelectrons and also provides the potential barrier to separate the charges to generate the current. In contrast, in the Grätzel dye-sensitized solar cell, the semiconductor is used solely for charge separation, and the photoelectrons are provided from a separate photosensitive dye. As shown in Figure 9.29 the solar cell consists of a TiO_2 layer forming a nanoporous structure with a dye (e.g., ruthenium-polypyridine) spread throughout its surface. The dye molecules are small, and in order to capture a reasonable amount of the incoming light, the nanoporous structure is used as a scaffold holding large numbers of the molecules in a 3D matrix, vastly increasing the number of molecules for a given surface area. The

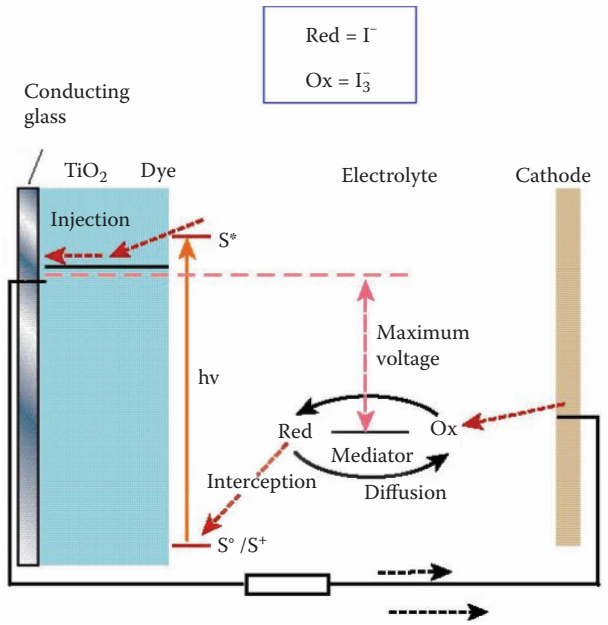

FIGURE 9.29 A liquid-junction solar cell: the dye-sensitized Grätzel design. The *S* energy levels represent the photosensitive dye levels.

charge separation is provided by the semiconductor-liquid junction contact. The TiO_2 layer sits on a transparent anode made of fluorine-doped tin oxide (SnO_2:F) deposited on the side of the glass plate facing the TiO_2 layer.

The electrolyte solution also holds a redox couple (e.g., I^-/I_3^-) mediator, located in the space between the dye-coated TiO_2 and a cathode, typically a thin film of platinum metal. Photons enter the cell through the transparent SnO_2:F window, and if they have enough energy, they are absorbed by the dye, creating an excited dye state. From this excited state an electron is "injected" into the conduction band of the TiO_2. This way, the dye molecule is oxidized, and it would decompose if it didn't quickly react with iodide in the electrolyte oxidizing it to form triiodide (dye regeneration reaction):

$$3I^- \rightarrow I_3^- + 2e^- \qquad \text{Reaction 9.6}$$

The reaction with iodide occurs very quickly compared with the recombination of the injected electron with the oxidized dye molecule, effectively preventing short-circuiting the solar cell. The injected electron then travels to the cathode via the external circuit, and the triiodide recovers its missing electron by diffusing through the solution to the

cathode, where it is reduced back to iodide (redox regeneration reaction):

$$I_3^- + 2e^- \rightarrow 3I^- \qquad \text{Reaction 9.7}$$

The electron injection process does not introduce a hole in the TiO_2, only an extra electron, and recombination of this electron directly from the TiO_2 to the electrolyte is not possible because of differences in energy levels (see Volume I, Chapter 7: if there are no overlapping energy levels, no reaction can occur). This is a very important property of the dye-sensitized Grätzel design: the electron-hole recombination that plagues the efficiency of traditional cells does not exist here. The potential used for external work in this solar cell is given by the following equation:

$$V_{ext} = E_F - V_{redox} \qquad (9.1)$$

The quantum efficiency of a Grätzel-cell is very high because the huge surface area of the TiO_2 nanostructure makes the chance that a photon will be absorbed very high, and the dyes are very effective at converting photons to electrons. Most of the losses are due to conduction losses in the TiO_2 and the clear anode, and the optical losses stem from the front electrode as well. The overall quantum efficiency is about 90%, with the "lost" 10% being largely accounted for by the optical losses in the anode. Although the dye is highly efficient in turning photons into electrons, only those electrons with enough energy to cross the TiO_2 bandgap result in current being produced. The bandgap is larger than that of silicon, which means that fewer of the photons in sunlight are usable for power generation. In addition, the electrolyte limits the speed at which the dye molecules can regain their electrons and become available for photoexcitation again. These factors limit the current generated by a liquid-junction solar cell; for comparison, a traditional silicon-based solar cell offers about 35 mA/cm², whereas a Grätzel cell offers about 20 mA/cm². The closest competitors in price-performance terms are the various thin-film approaches, which are currently somewhat more developed commercially.

The dyes used in early experimental Grätzel cells were sensitive only in the high-frequency end of the solar spectrum (ultraviolet and blue). Newer versions have a much wider frequency response; notably, the triscarboxy-terpyridine ruthenium complex $[Ru(2,2',2''\text{-}(COOH)_3\text{-terpy})(NCS)_3]$ is efficient right into the low-frequency range of red and infrared (IR) light. The wide spectral response results in the dye having a deep brown-black color, and it is referred to simply as *black dye*.[39] These polymers also are also sensitive to infrared are called *thermovoltaics*, and they generate electricity from both light and heat. Current Grätzel cells demonstrate a conversion efficiency of about 11%, whereas common low-cost commercial panels operate between 12% and 15%. Flexible thin-film cells are typically around 8%. Perhaps the major disadvantage of a liquid-junction solar cell is the use of liquid electrolytes, which brings leakage and corrosion problems, as well as temperature stability problems. At low temperatures, the electrolyte can freeze, ending power production and potentially leading to physical damage. Higher temperatures cause the liquid to expand, making sealing the cells a serious problem.

To avoid the above problems of liquid-junction solar cells, several research groups aim to produce a hybrid organic-QD PV device as the solid analog to the Grätzel cell. Researchers at the University of Toronto mixed lead sulfide (PbS) QDs with the polymer poly(2-methoxy-5-[2'-ethylhexyloxy-p-phenylenevinylene]) (MEH-PPV). Wrapping MEH-PPV around the QDs shifted the polymer's absorption into the infrared: on its own the polymer absorbs between ~400 and ~600 nm, and the QDs have absorption peaks that can be tuned from ~800 to ~2000 nm (see Figure 9.30).[40] The best efficiency registered thus far with this approach is 1.6%.[41]

In 2000, Nozik from the National Renewable Energy Laboratory in Golden, Colorado, predicted that theoretically, QDs could increase the efficiency of solar cells through multiple exciton generation.[42] "We have shown that solar cells based on QDs theoretically could convert more than 65 percent of the sun's energy into electricity, approximately doubling the efficiency of solar cells," said Nozik.[42]

In 2004, Schaller and Klimov from the Los Alamos National Laboratory in New Mexico were the first to demonstrate this phenomenon experimentally, using QDs made of lead selenide.[43] Multiple excitons

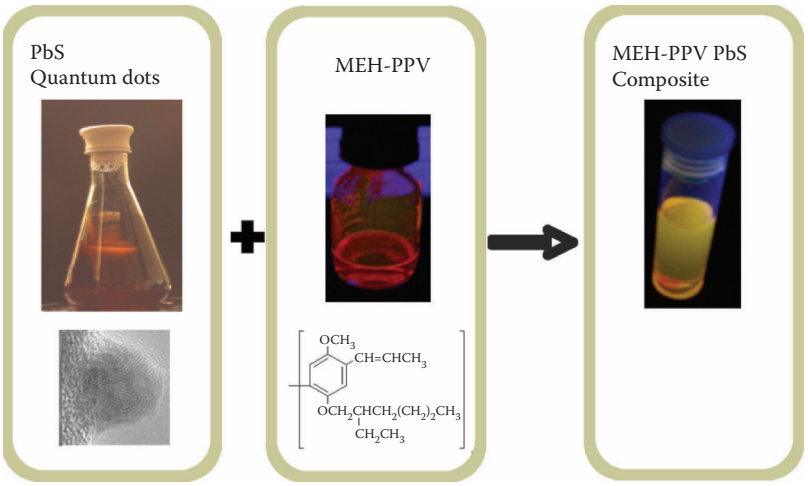

FIGURE 9.30 Lead sulfide (PbS) quantum dots are mixed with poly(2-methoxy-5-[2′-ethylhexyloxy-p-phenylenevinylene]) (MEH-PVV) to make a MEH-PPV PbS composite.[40]

start to form simultaneously as soon as the photon energy reaches twice the bandgap, and a group of researchers led by Nozik demonstrated that the absorption of a single photon by 2.9 nm PbSe QDs yielded not one exciton but three when the energy of the photon absorbed is four times that of the bandgap[43] (a quantum yield of 300%). Quantum dots made of PbS also showed the same phenomenon.

Quantum wells, as we saw in Volume I, Chapters 3 and 5, are ultrathin layers (nanostructures) of a narrower bandgap material (e.g., a GaAs well) sandwiched between regions of wider bandgap (e.g., AlGaAs barrier). They are made possible by the development of modern crystal growth techniques such as molecular beam epitaxy (MBE) and metal-organic vapor phase epitaxy (MOVPE). We also saw how quantum well lasers work at high forward bias and how quantum well photodiodes operate at reverse current and reverse bias. Quantum well solar cells (QWSCs) work in the forward bias and reverse current quadrant of the current-voltage plot, where power can be extracted.[44] In Figure 9.31 a first material with bandgap E_g is contacted with another material of bandgap (E_q) smaller than E_g, i.e., $E_q < E_\gamma < E_g$. The idea, as with a tandem solar cell, is that the quantum wells absorb light of energy below the bulk bandgap, E_g.

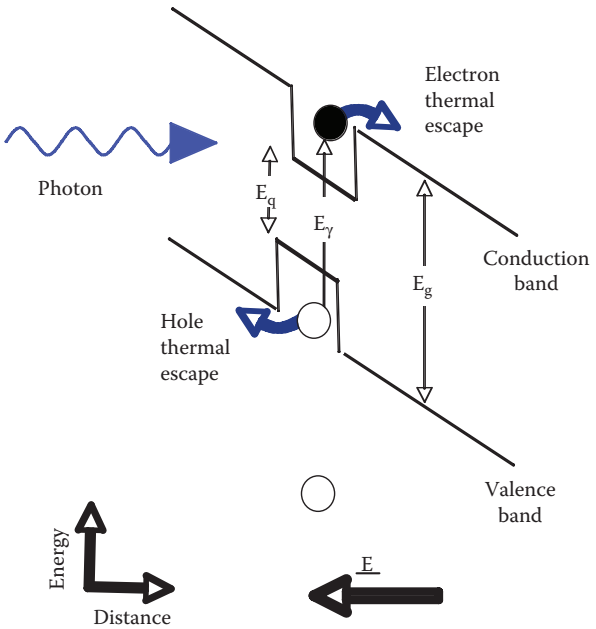

FIGURE 9.31 Schematic illustrating the quantum well solar cell.

In the simplest QWSC, several quantum wells are added to the *i*-region of a conventional p-i-n solar cell of wider bandgap (E_g). The quantum wells do absorb light of energy below the bulk bandgap E_g. If carriers escape from the wells before recombining, they enhance the output current, and short-circuit current (I_{sc}) can be strongly enhanced. The open-circuit voltage (Voc) is reduced, but the cell's efficiency is considerably enhanced.

Energy Scavenging (Harvesting)

MEMS devices either feature onboard power sources such as batteries, capacitors, fuel cells, radioactive elements, etc.; are powered by energy that is beamed in on purpose; or harvest energy from their own

environment. Energy harvesting is the process of capturing minute amounts of energy from one or more naturally occurring energy sources and storing that energy for later use. Harvestable energy sources for a MEMS device include mechanical (from sources such as vibration, mechanical stress, and strain, captured by ratchets and springs), thermal (waste energy from furnaces, heaters, and friction, captured by thermocouples, bimorphs, and thermoelectrics), light (captured from sunlight or room light via photosensors, photodiodes, or solar panels), electromagnetic (from inductors, coils, and transformers, captured by coils), natural (wind and ocean currents), the human body (a combination of mechanical and thermal energy naturally generated from bio-organisms or through actions such as walking and sitting), and other energy from chemical and biological sources. All these energy sources are virtually unlimited and essentially free, if they can be captured at or near the system location.

Naturally occurring temperature gradients are one potential source of power. Stark and Stordeur,[45] for example, demonstrated a thermoelectric device that can produce 15 mW of power from a 10°C temperature difference. The thermal gradient principle is employed in satellites, which are hot on the side turned toward the sun but cold on the side facing away from the sun. A satellite can be powered by the energy thus generated for up to thirty years. The principle also operates in reverse: thermoelectric elements can produce cold from electricity and are used these days to cool the interiors of computers. In the 1960s, it was believed that if transistors could replace vacuum tubes for electronics, then surely thermoelectrics could replace refrigerators. Requirements for a good thermoelectric (TE) material are a high figure of merit, ZT; this requires a high Seebeck coefficient, S, a high electrical conductivity, σ, and a low thermal conductivity, κ (see Equations 8.70–8.73). Unfortunately, ZT has to be improved from ~0.9 to 3 or higher to become commercially attractive. (ZT needs to improve to over 1.3 at 300 K for a major impact in electronics cooling and to around 2.5 for a revolutionary impact in air conditioning and power from waste heat.)

Some researchers have focused on scavenging power from the human body. Shenck and Paradiso,[46] for example, did create shoe inserts capable of generating 8.4 mW of power under normal walking conditions. [See also MIT Media Lab's Parasitic Power Harvesting project for devices built into a shoe (http://www.media.mit.edu/resenv/power.html).]

Mechanical vibrations are another promising power source. Scavenging the power from commonly occurring vibrations for use by electronics is both feasible and attractive for certain applications. Three popular methods to harvest energy from vibrations are piezoelectric, capacitive, and inductive. In the piezoelectric method, the strain in a piezoelectric material causes a charge separation (voltage across capacitor). Ottman et al.[47] have designed and optimized power circuitry to be used with a piezoelectric vibration-based generator. In a capacitive pick-up, a change in capacitance causes either a voltage or charge increase. Roundy et al.[48] have published electrostatic MEMS designs with simulated power outputs in the range of tens of microwatts per cubic centimeter. With an inductive pick-up, a coil moves through a magnetic field causing current in a wire. Amirtharajah, Chandrakasan, and coworkers[49] demonstrated an electromagnetic vibration-to-electricity converter with a 160-cm^3 volume ($4 \times 4 \times 10$ cm) that produces 400 mW of power (or 2.5 mW/cm^3). Table 9.7 compares the features of different vibrational harvesting techniques. Currently, a piezoelectric approach with PZT is the most popular because of its compact configuration and compatibility with MEMS, but its inherent limitations, including aging, depolarization, brittleness, and high-output impedance, limit many applications.[50]

As Goemans points out, the possibility of converting motion into electrical energy can be very attractive for cases where battery replacement is unacceptable, kinetic energy is abundantly available, and space is not too limited.[6] He lists biomedical implants, tire pressure monitoring systems, and electronic locks as potential application areas.[6] Some power harvesting systems are compared with batteries, fuel cells, solar power, and nuclear power in Table 9.8.

Table 9.7 Summary Comparison of the Different Vibrational Types of Harvesting Mechanisms[50]

Type	Advantages	Disadvantages
Electromagnetic	• No need of smart material • No external voltage source	• Bulky size: magnets and pick-up coil • Difficult to integrate with MEMS • Maximum voltage of 0.1 V
Electrostatic	• No need of smart material • Compatible with MEMS • Voltages of 2~10 V	• External voltage (or charge) source • Mechanical constraints needed • Capacitive
Piezoelectric	• No external voltage source • High voltages of 2~10 V • Compact configuration • Compatible with MEMS • High coupling in single crystals	• Depolarization • Brittleness in PZT • Poor coupling in piezo film (PVDF) charge leakage • High-output impedance
Magnetostrictive	• Ultrahigh coupling coefficient >0.9 • No depolarization problem • High flexibility • Suited to high-frequency vibration	• Nonlinear effect • Pick-up coil • May need bias magnets • Difficult to integrate with MEMS

Table 9.8 Energy Harvesting Compared with Batteries, Fuel Cells, and Nuclear Power

	Power (Energy) Density	Source of Estimates
Batteries (zinc-air)	1050–1560 mWh/cm^3 (1.4 V)	Published data from manufacturers
Batteries (lithium ion)	300 mWh/cm^3 (3–4 V)	Published data from manufacturers
Solar (outdoors)	15 mW/cm^2 – direct sun 0.15 mW/cm^2 – cloudy day	Published data and testing
Solar (indoor)	0.006 mW/cm^2 – my desk 0.57 m/Wcm^2 – 12 in. under a 60 W bulb	Testing
Vibrations	0.001–0.1 m/Wcm^3	Simulations and testing
Acoustic noise	3E-6 mW/cm^2 at 75 Db sound level 9.6E-4 mW/cm^2 at 100 Db sound level	Direct calculations from acoustic theory
Passive human powered	1.8 mW (shoe inserts >> 1 cm^2)	Published study
Thermal conversion	0.0018 mW – 10 deg. C gradient	Published study
Nuclear reaction	80 mW/cm^3 1E6 mWh/cm^3	Published data
Fuel cells	300–500 mW/cm^3 ~4000 mWh/cm^3	Published data

Fractal Power

Introduction

In this section, we show how the use of fractal-like electrodes in batteries and fuel cells minimizes the internal resistance while maximizing surface-to-volume ratios. We also demonstrate how C-MEMS techniques show great promise for use in the fabrication of such fractal electrodes for electrochemical applications.

Fractals and Fractal Dimensions

A fractal is a rough or fragmented geometric shape, each part of which is, at least approximately, a smaller copy of the whole. Another definition holds that a fractal is an irregular geometric object with an infinite nesting of structure at all scales. Fractals are said to be self-similar because no matter what the scale of observation, whether we zoom in or out, we appear to be seeing the same object. Fractals came to the public attention through the stunning abstractions generated in computer screen savers by the famous Mandelbrot set. Mandelbrot* introduced the idea of

* As a child in France, Mandelbrot wondered how to use the smooth regularities of Euclidean shapes to model the complexity of the world he saw around him. Where were the circles in nature? Where were the parallel lines and infinite planes? He concluded "clouds are not spheres, mountains are not cones, coastlines are not circles, and bark is not smooth nor does lightning travel in a straight line."[51]

fractals in a paper that asked, how long is the coastline of Great Britain?[51] The coastline is irregular, so a measure with a straight ruler provides an estimate only. The estimated coastal length, *L*, equals the length of the ruler, *s*, multiplied by *N*, the number of such rulers needed to cover the measured object. Mandelbrot realized that the smaller his measuring stick, the longer the coast would turn out to be and that using molecular distances, the coast would have an infinite length. This means, Mandelbrot conjectured, that the Euclidean dimension, *D*, of a coastline is between the one dimension of a straight line and the two of a plane.

If we take an object residing in Euclidean dimension *D* and reduce its linear size by 1/*r* in each spatial direction, its measure (length, area, or volume) would increase by *N* times the original, with *N* given by the following equation:

$$N = r^D \tag{9.2}$$

This is pictured in Figure 9.32.

The German mathematician Felix Hausdorff introduced a more general treatment of dimension *D*. He pointed out that taking the log of both sides of Equation 9.2 one obtains the following:

$$\log(N) = D \log(r) \tag{9.3}$$

And if we solve for *D*, we get the following:

$$D = \log(N)/\log(r) \tag{9.4}$$

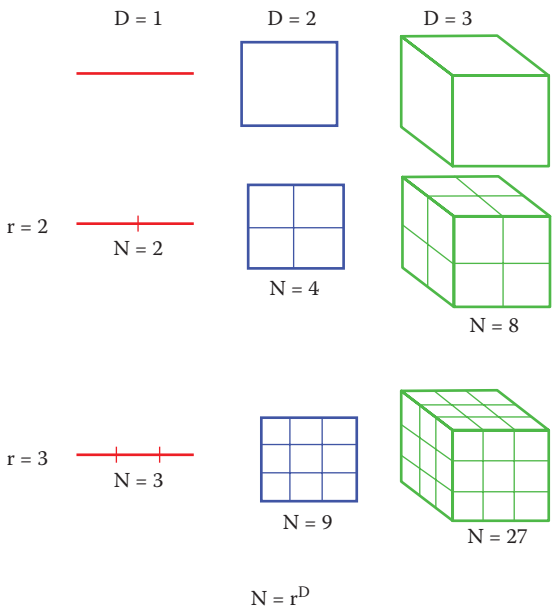

FIGURE 9.32 Fractal dimensionality: the Hausdorff dimension.

The point that emerges is that if dimensionality, *D*, is examined this way, *D* need not be an integer, as it is in Euclidean geometry. It could be a fraction, as it is in fractal geometry. This approach has proved very useful for describing all types of natural objects and for evaluating trajectories of dynamic systems.

It was Lewis Fry Richardson who first noted the regularity between the length *L* of coastlines, rivers, continental boundaries, etc., and the scale size *r*: when plotted in a log-log plot, a linear relation is obtained between log [*L*(*r*)] and log(*r*). Mandelbrot assigned the term (1 – *D*) to the slope of such a log-log plot, or:

$$\log[L(r)] = (1 - D)\log(r) + b \tag{9.5}$$

where *D* is the fractal dimension and *b* a constant.

For Great Britain, the slope 1 – D = –0.24, approximately, or D = 1.24, a fractional value. The coastline of South Africa is very smooth, virtually an arc of a circle, and the slope is very near zero, and this gives a fractional dimension D = 1 – 0 = 1. This makes sense because the coastline is very nearly a regular Euclidean object, a line, which has dimensionality of 1. In general, the "rougher" the line, the steeper the slope and the larger the fractal dimension (the fractal dimension for the Nile delta is 1.4; that of the Amazon basin is 1.85).

Hausdorffian dimensionality is further illustrated by considering the Koch curve shown in the inset of the header of this chapter. To make a Koch curve, a one-dimensional (1D) line is buckled to take on some fractional dimension between 1D and 2D. We begin with a straight line of length 1, called the *initiator*. We then remove the middle third of the line, and replace it with two lines that each have the same length (1/3) as the remaining lines on each side. This new form is called the *generator*, because it specifies a rule that is used to generate a new form. The rule says to take each line and replace it with four lines, each one-third the length of the original. We can do this iteratively without end; the length of the curve increases with each iteration, and it asymptotically approaches infinite length. If we treat the Koch curve as we did the coastlines and continents, the relation between log[*L*(*r*)] and log(*r*) for the Koch curve gives us D = log(4)/log(3) = 1.26. It is a number that the Koch curve approaches

as it becomes ever more finely broken over all possible scales. A huge number of everyday phenomena do seem ruled by such power-laws rather than Gaussian statistics. Some are well-known examples, such as earthquakes and species extinctions. Fractal organization is to be found in all kinds of dissipative structure—structures that "chaotically" branch in order to dump a load of energy as fast as possible (see Chapter 3, "Self-Organization").

Fractals in Nature

Nature always strives for the highest efficiency in all its organisms, and fractal-like networks are nature's answer to this maximization problem, literally "giving life an additional dimension."[52] Fractals in nature represent the geometry of irregular shapes and chaotic systems: trees, rivers, brains, lungs, the cardiovascular system, clouds, and coastlines all can be described by fractals.

In nature, the fundamental equation that describes scaling of various variables with relation to body mass, we saw in Chapter 7, is an allometric equation of the following form:

$$V = aM^b \tag{7.1}$$

where V is the variable in question, a is a constant, and b is the scaling exponent (in Chapter 7 we used $y = bx^a$). The fascinating empirical observation that has perplexed many scientists and has been a source of much debate is the fact that the exponents (b in Equation 7.1) of many variables, including cellular metabolism ($b = -1/4$), heartbeat ($b = -1/4$), maximal population growth ($b = -1/4$), lifespan ($b = 1/4$), blood circulation ($b = 1/4$), embryonic growth/development ($b = 1/4$), metabolic rates of entire organisms ($b = 3/4$), cross-sectional areas of mammalian aortas ($b = 3/4$), and cross-sectional areas of tree trunks ($b = 3/4$) are multiples of 1/4 instead of 1/3.[52] Pure geometric scaling of area (l^2) and volume (l^3) leads to a scaling constant of 2/3, but as Max Kleiber discovered in the early 1930s, the metabolic rates of entire organisms (which should scale with area) scale with respect to body mass (which should scale with volume), with a scaling constant of 3/4. This relationship is now referred to as *Kleiber's law* (see Figure 7.4). We also saw that West et al.[52] proposed a general model for this extra "fourth dimension". By modeling the cardiovascular system as a fractal-like network that ends in terminal units (capillaries) of the same size, they have shown that minimizing the work that the heart performs in pulsatile systems leads to the proper scaling constants that are empirically observed.

Fractals in Electrochemistry

Just as nature has benefited from fractal structures in almost all of its organisms, biomimetic fractal designs in electrochemical devices such as power conversion devices and sensors can also lead to benefits in scaling.

Fractals are an optimal geometry for minimizing the work lost due to the transfer network while maximizing the effective surface area. In many electrochemical systems, it is advantageous to have a large surface-to-volume ratio, while needing to transfer the signal or power effectively to an electrical network. Electrochemical energy conversion devices, such as fuel cells and some types of batteries, as well as sensors, such as glucose sensors, are examples of such applications. Miniaturization of these electrochemical devices to create miniature electrochemical devices poses several problems due to scaling. One issue is that there is a problem of increasing internal resistance in miniature 3D devices. In cases where an electrode is composed of materials that are excellent electrical conductors, such as metals, the internal resistance contribution of the electrode is minimal and can be ignored, but if the electrode is composed of carbon or another material that is a optimal electrochemical material, but not necessarily an optimal electrical material, the internal resistance contribution due to the electrodes can be significant.[53]

The resistance of a bulk or porous network scales inversely to the length scale l if scaled isometrically, as illustrated in Figure 9.33a. Figure 9.33b illustrates the scaling involved when scaling area with a constant thickness. Since the volumes of the structures can be written as follows:

$$V = l^3 \qquad \text{for Figure 9.33a} \tag{9.6}$$

$$V = tl^2 \propto l^2 \qquad \text{for Figure 9.33b} \tag{9.7}$$

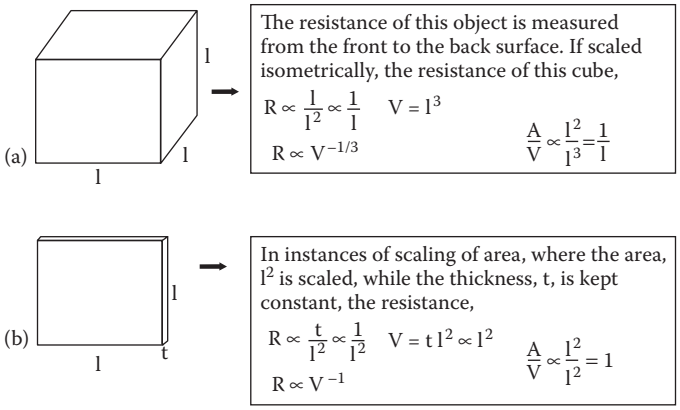

FIGURE 9.33 Scaling of a cube (a) and a sheet (b).

From this figure it can be concluded that resistance of a bulk material scales as follows:

$$R \sim V^{-1/3} \qquad \text{for Figure 9.33a} \qquad (9.8)$$

when scaling isometrically and as:

$$R \sim V^{-1} \qquad \text{for Figure 9.33b} \qquad (9.9)$$

when scaling area only.

The surface area and the scaling of the surface-to-volume ratios of the two cases in Figure 9.33 are as follows (assuming $t \ll l$).

$$\frac{A}{V} \propto \frac{l^2}{l^3} = \frac{1}{l} \qquad \text{for Figure 9.33a} \qquad (9.10)$$

and:

$$A = 4lt + 2l^2 \approx 2l^2 \text{ and } \frac{A}{V} \propto \frac{l^2}{l^2} = 1 \qquad \text{for Figure 9.33b} \qquad (9.11)$$

The surface-to-volume ratio of a bulk material is inversely proportional to the length scale ($1/l$) when scaling isometrically in three dimensions and is invariant (1) when scaling in two dimensions.

In the case of conventional Li-ion batteries and fuel cells, where the dimensions of the fundamental building blocks (the anode/electrolyte/cathode sandwich) are smaller than the final device dimensions and need to be scaled up, areal scaling is advantageous. As can be seen from Equations 9.8 to 9.11, 2D scaling from a small fundamental building block results in lower internal resistance and higher effective area compared with an isometric three-dimensional scaling approach. Indeed, commercial Li-ion batteries and fuel cells are composed of many layers of anode, cathode, and electrolyte that are rolled, folded, or stacked on top of each other. In the case of miniature power devices, where conventional methods of rolling, folding, and stacking are not applicable, microfabrication deposition techniques have been used to create thin-film batteries. Although applicable in some circumstances, there are instances where a 3D package is needed. As mentioned by Long et al.[7], the limiting factor of increasing the height of 3D miniature batteries is the increased internal resistance of the high-aspect-ratio structures. The use of better electronic and ionic conductors, in addition to the optimal geometries, determines the practical upper limit of these devices. This author believes that fractal networks can prove to be a more favorable architecture for miniature electrochemical devices. Other than the purely electrical advantages, fractal architectures provide a middle ground between high-surface-area electrodes composed of nanomaterials and solid electrodes. Although the high surface area of nanomaterial electrodes does increase performance in many areas, much of the volume of the entire battery can be "wasted" because of the electrolyte around the electrode. In a fractal electrode, much of the volume that would be composed of electrolyte is replaced with electrode material.

The approach used by West et al.[52] to model the fractal nature of the cardiovascular system is mirrored and directly converted to that of a fractal network of electrically conductive material in the model of Park et al.[53] The purpose of this exercise was not to model a specific system but to provide an idealized zeroth-order approximation for a fractal electrochemical system.

There are three general assumptions made by West et al.[52] The first assumption is that a fractal-like branching network is required to supply a volume effectively. In an electrochemical device, it is important to maximize the use of space. For example, fuel cell engineers strive to maximize the density of triple phase boundaries (most of the time by increasing the effective surface area), and batteries and sensors benefit from large surface-to-volume ratios because, in many cases, the chemistry is largely a surface phenomenon (limited by a process near the surface).

In situations where the reaction is limited by mass transfer, the mass transfer problem can be alleviated by reducing the distance the reactants need to travel, i.e., by spreading the reaction sites throughout the entire volume of the device. Just as capillaries are spread out throughout an organism because each capillary can only supply a certain volume of space with oxygen and nutrients, it is beneficial to spread out the reaction surface throughout the volume in an electrochemical device. It is possible to spread out the effective surface area throughout a 3D space using a sponge-like or web-like material composed of fibers or particulates, but in many cases, it becomes difficult to transfer the charge from and to the reaction sites.

Space-filling fractal networks can work to ensure that there is efficient charge transfer from a huge effective surface area to a current collector. The second assumption is that the smallest fractal structure is a size-invariant unit independent of the total volume. There are physical and practical limitations in size for all materials, even though these limits may differ from material to material. Nanoparticles, nanofibers, nanotubes, and other nanoscale materials are all examples of a fundamental building block. The final assumption is that energy used to distribute resources should be minimized.

Figure 9.34 illustrates the fractal electrochemical network with three branches (fractal levels) and a branching factor, n, of two as assumed by our team for our fractal model. N_k is the number of elements at fractal level k, and each level has $N_k = n^k$ elements; s is the fractal level for the smallest elements. J_{limit} is the maximum current density of any element, and R_k, ρ, l_k, A_k, r_k, v_k are the resistance, resistivity, length, area, radius, and service volume, respectively, for a fractal element at level k. A cylindrical geometry for each element is assumed.[53]

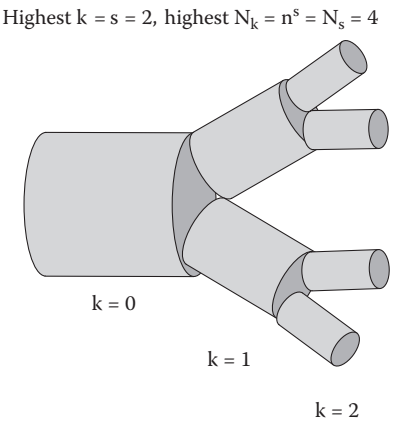

FIGURE 9.34 A simple fractal electrode.[53]

In electrochemical devices, there is loss of energy and an associated voltage drop due to the internal resistance. Minimization of this internal resistance is key to achieving efficient power transfer. This becomes more crucial as the current to the electrical load becomes larger because of Ohm's law:

$$E = IR \tag{9.12}$$

where E is the electrical potential, I is the current, and R is the resistance. In situations where the electrochemical system is limited by surface phenomena, there is a limiting interface current density J_{limit}. The total current, I_{total}, flowing through an electrode with a total surface area (total exchange area) of A_{total} operating in a surface-phenomena-limited regime is as follows:

$$I_{total} = J_{limit} A_{total} \tag{9.13}$$

We define the fractal level with the smallest elements as level s and N_k to be the number of elements at level k. We derived that the total exchange surface area, A_{total}, is proportional to the number of the smallest elements, N_s:

$$I_{total} \propto N_s \tag{9.14}$$

The total current is thus proportional to the number of the smallest elements within the fractal network. Obviously, maximizing the number of small elements within a fractal structure is desired. We also derived the following:

$$R_{total} \propto \frac{1}{N_s} \tag{9.15}$$

Again, as with Equation 9.14, maximizing the number of the smallest elements is desirable. This ensures that current is maximized, while the internal resistance is minimized. From Ohm's law and Equations 9.14 and 9.15, it can be concluded that if a fractal network geometry is used, the voltage drop across the entire structure is as follows:

$$E_{total\ internal\ voltage\ drop} = I_{total} R_{total} = \text{constant} \tag{9.16}$$

The power dissipation, in turn, scales with N_s:

$$P = E_{total}\, I_{total} = I^2_{total}\, R_{total} \propto N_s \qquad (9.17)$$

We also calculated that V_0, the volume of the liquid where effective exchange occurs with the electrode, the exchange volume can take place as given by the following (for details see Park et al.[53]):

$$V_0 \propto N_s \qquad (9.18)$$

Combining Equation 9.18 with Equations 9.14, 9.15, 9.16, and 9.17, one can then summarize the volumetric scaling of the electrical characteristics of a fractal network:

$$I_{total} \propto V_o \qquad (9.19)$$

and:

$$R_{total} \propto \frac{1}{V_o} \qquad (9.20)$$

So that $E_{total\ internal\ voltage\ drop} = I_{total}\, R_{total} = \text{constant}$ again, and:

$$P \propto V_0 \qquad (9.21)$$

We also obtained the following:

$$\frac{A_{total}}{V_0} \approx \text{constant} \qquad (9.22)$$

In other words the surface-to-volume ratio of a fractal electrode does not change as the volume changes.

Comparing Equation 9.20 with Equation 9.9, it can be concluded that the resistance of fractal electrodes scale similar to a thinly layered structure, not to an isometrically scaled volumetric geometry, and comparing Equation 9.22 with Equation 9.11, the surface-to-volume ratio of a fractal electrode does not change as the volume changes; again the fractal geometry scales more like a layered film than a volumetric electrode. The scaling of the electrical properties of a fractal electrode is summarized and compared with that of a 2D or 3D electrode in Table 9.9.

Table 9.9 Scaling of a Fractal Compared with Two-Dimensional and Three-Dimensional Scaling

Fractal	3D Scaling	2D Scaling
$I_{total} \propto V_0$		
$R_{total} \propto \frac{1}{V_o}$	$R \propto V^{-1/3}$	$R \propto V^{-1}$
$E_{total\ internal\ voltage\ drop} = \text{constant}$		
$P \propto V_0$		
$\frac{A_{total}}{V_0} \approx \text{constant}$	$\frac{A}{V} \propto \frac{l^2}{l^3} = \frac{1}{l}.$	$\frac{A}{V} \propto \frac{l^2}{l^2} = 1$

C-MEMS Fractals

The author believes that C-MEMS[54–57] technology is an attractive path toward the fabrication of 3D fractal-like carbon electrodes. C-MEMS describes a fabrication technique in which carbon devices are made by treating a prestructured organic material with high temperatures (typically 900°C and higher) in an inert or reducing environment. The details of the fabrication process are described in Chapter 5.

Fabricating a multilevel fractal structure that is idealized by the model that we have described above (and shown in Figure 9.34) is not a trivial issue. One reason behind the difficulty of this task is that the tools that are used for 3D microfabrication do not apply over a large range of length scales. Hybrid 3D fabrication techniques that combine different fabrication methods are therefore required (see Figure 3.11). An example hybrid method is briefly described below for the construction of a 3D fractal-like C-MEMS structure.

Example 9.3: Doped Photoresist Method to Make Fractal-Like Carbon Structures

In this method, standard photolithography is used on a photoresist (SU-8) premixed with carbon nanofibers (CNFs). The CNFs (Hawaii Industrial Labs) are first mixed with the SU-8 100 resin (1% by weight). The doped photoresist is then spin-coated onto a silicon wafer to an approximate 100-μm thickness. The standard photolithographic process to pattern the desired cylindrical photoresist posts then follows. After development, the posts exhibit a few clumps of CNFs on their surfaces that are partially embedded inside the SU-8. Pyrolysis of these structures converts the entire structure into carbon, with a thick coat of clumps of CNFs now covering the side walls of the posts. The CNFs shown can withstand the pyrolysis process and stay attached to the carbon posts. The process of all the

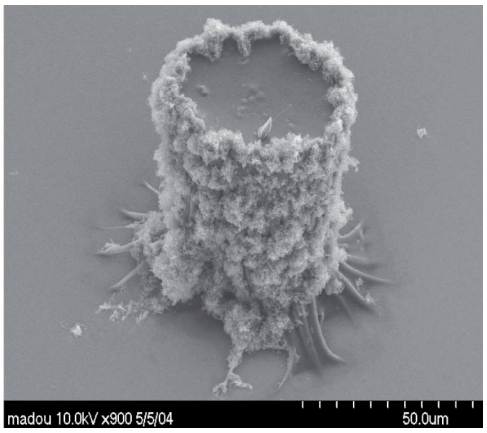

FIGURE 9.35 Scanning electron microscope image of a carbon post with nanofibers.

nanofibers migrating to the cylinder walls during pyrolysis is not yet understood. Figure 9.35 shows a scanning electron microscope image of this fractal-like structure. This is a direct attempt at mimicking the branching that we have mathematically modeled above (see Figure 9.34). Obviously this represents a rather poor fractal-like structure, with only two possible length scales, i.e., 100 μm (for the posts or tree stems defined by lithography) and nanometer-sized CNFs (the "branches").

For a sensor application, a single tree-like carbon microelectrode would already make for a big improvement over current sensor electrodes since it comes with the largest surface area while keeping the internal resistance minimal. Such a tree-like structure could be decorated with catalyst molecules like the decorations on a Christmas tree.

As illustrated in Figure 9.36, plant matter can be converted into carbon, much as charcoal is formed. One could then envision the use of natural occurring organic matter-based fractals to make carbon fractals.

In order to create a truly C-MEMS biomimetic energy conversion device, the anode and cathode, both fractal structures, must be intertwined while maintaining a pinhole-free electrolyte separation between the two in a manner similar to the blood vessels and air pathways in a mammalian lung. This may prove to be the most difficult task in arriving at a fully C-MEMS fractal battery or fuel cell.

Brains in Miniature Devices

Introduction

Before considering the implementation of computing power or brains in miniaturized systems, such as in microrobots, it is a good idea to briefly look at the state of the art in computer development in general and compare it with nature's arsenal using neurons and brains. After this introductory section, we consider the latest developments in artificial intelligence (AI). We discuss how both bottom-up and top-down approaches to AI might affect MEMS. Complexity theory and artificial life are considered next as two examples of bottom-up approaches to building AI that feature the self-organizing or emergent properties touched upon in Chapter 3. Artificial neural networks represent a bottom-up approach heavily dependent on learning cycles. Electronic noses and tongues have already been developed on the basis of such neural nets. As in the case of machining, we will learn that bottom-up approaches for embedding intelligence in MEMS are gaining more and more interest.

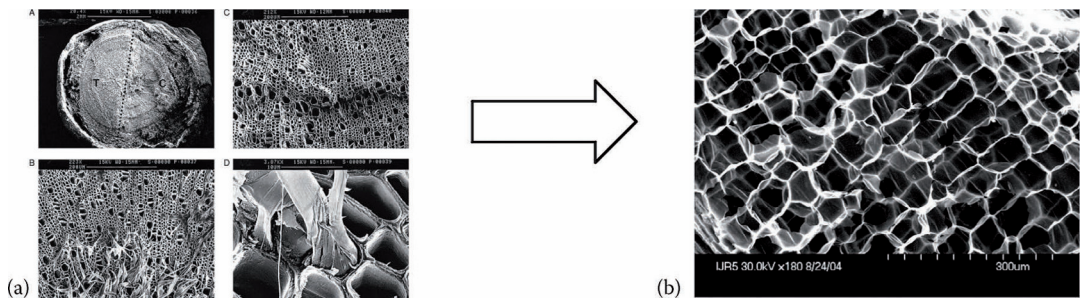

FIGURE 9.36 In the charcoal process, the structure of the plant cells is preserved. The high-temperature process is carried out in an oxygen-starved environment. (a) Twig of a tree with plant cells. (b) Charcoal. The original plant cell walls are preserved in the carbon.

State of the Art in Computer Development

IBM's ASCI White is a 12.3 trillion calculations per second machine the size of two basketball courts; it weighs 106 tons and cost $110 million. The machine runs programs on 8192 central processing units (CPUs) in parallel, resides at the Lawrence Livermore National Laboratory, and is the property of the US Department of Energy. Today, the most ambitious development effort to reach petaflop computers (*flops* is an acronym for floating point operations per second) is being carried out by a consortium headed by Caltech. The new system will have 150-GHz chips, cooled to near absolute zero. Because of their size and cost, such systems obviously remain out of range for MEMS. Closer to home are PCs. Intel's 0.18-μm manufacturing process is used to produce Coppermine Pentium III chips for PCs, which, when working at full speed, are as fast as 1.5 GHz. As we have seen in Volume II, Chapters 1 and 2, Moore's law will continue to hold for the next three to four MOSFET generations, reducing any mainframe to PC status eventually. In Volume I, Chapter 4, we saw how the fundamental thermodynamic limit of a MOSFET switch in a computer is the energy required to produce a binary transition that can be distinguished. The von Neumann-Landauer formula sets that theoretical limit (at 300K) as:

$$E_{bit} > kT \ln 2 \approx 18 \text{ meV}$$

(Volume I, Equation 4.70)

If a MOSFET switch consumes an amount of free energy E and performs N useful operations, the energy efficiency, we saw, is given by the following:

$$\eta = E/N \qquad \text{(Volume I, Equation 4.71)}$$

with η in units of operations per unit energy, or operations/second/watt. Using the thermodynamic energy limit per bit, this, in theory, enables an energy efficiency of $\eta = 3.5 \times 10^{20}$ operations/second/watt. In practice, using the case of 90 nm VLSI technology as an example, E is on the order of 1 fJ (femtojoule) and $\eta = 10^{15}$ operations/second/watt. This means that theoretically we can increase computing efficiency by a factor of more than 100,000. MOSFET downscaling is hampered by energy level quantization, though. The quantum mechanical limits on MOSFET scaling, based on the Heisenberg uncertainty principle, we summarized as follows:

$$x_{min} = \frac{\hbar}{\Delta p_x} = \frac{\hbar}{\sqrt{2m_e\ E_{bit}}} = \frac{\hbar}{\sqrt{2m_e\ k_B T \ln 2}} = 1.5 \text{ nm}$$

(Volume I, Equation 4.72)

which puts a fundamental limit on the integration density. For a limit on switching speed, we calculated the following:

$$\Delta E \Delta t \geq \frac{h}{2\pi} = \hbar$$

$$\Rightarrow \tau \sim 0.04 \text{ ps or } 25 \text{ Tbits/second}$$

(Volume I, Equation 4.73)

Thus, quantum mechanics allows for a very small switch, but other factors, such as a material's temperature tolerance range, will limit before this fundamental limit sets in. Maintaining Moore's exponential increase in transistor count, however, will become progressively more difficult and expensive. Cost may ultimately become more significant than technical boundaries, since it dictates every investment in research and development. Memory storage devices are improving even faster than ICs, but they will also encounter similar obstacles. This has fueled the drive to look beyond silicon and current transistor logic to totally new areas, such as optical, DNA, and quantum computing.

Radical modifications to current computer architecture are under consideration today. For example, it is the electron charge that is used in the conventional semiconductors that comprise the CPUs and dynamic random access memories (DRAMs) in computers today. For the nonvolatile memory, magnetic disk drives are used, and these rely on the spin state of electrons to store large amounts of information and in particular to preserve information when the computer is shut down. There is now the possibility of developing devices that simultaneously use the spin and charge of the electron to vastly increase the capability of information processing, in what are called *spintronics* (spin-based electronics) *devices*. All spintronic devices behave according to this simple scheme: 1) information is stored (written) into spins as a particular

spin orientation (up or down), 2) the spins, being attached to mobile electrons, carry the information along a wire, and 3) the information is read at a terminal. Spin orientation of conduction electrons survives for a relatively long time (nanoseconds, compared with tens of femtoseconds during which electron momentum decays), which makes spintronic devices particularly attractive for memory storage, magnetic sensors applications, and quantum computing, where electron spin represents a bit (called a *qubit*) of information. A qubit can exist not only in a state corresponding to the logical state 0 or 1 as in a classical bit, but also in states corresponding to a blend or superposition of these classical states. In other words, a qubit can exist as a zero, a one, or simultaneously as both 0 and 1, with a numerical coefficient representing the probability for each state. Four pairs of classical bits are needed to represent the same information as 1 pair of qubits. With eight qubits we can represent every number between 0 and 255 simultaneously. This allows for the compression of massive amounts of data. Quantum computing thus takes advantage of the concepts of superposition of states and entaglement introduced in Volume I, Chapter 3. This gives rise to many more states of the system, and thus in principle the ability to represent much more information without increasing the number of components—providing that it is possible to devise a way for the states of the system to interact quantum mechanically.[58]

Quantum computers with a handful of qubits have been made, but it seems hard to envision one with more than ten qubits. These early prototypes tend to suffer from decoherence after around 1000 operations. An interesting approach is to work with electrons on nanodots instead of on individual atoms as qubits. Nanowires are used to connect these nanodots and provide a physical entanglement. Providing entanglement through a physical connection between individual atoms is impossible, but between nanodots it can be done and it might avoid decoherence.

Research in these computing alternatives is well under way and even though non-silicon-based processors will not appear for many years to come, it seems quite certain that information technology will not be stopped when Moore's law ceases to be valid. For integrating computing power in MEMS, there are already good solutions today. The evolution of ICs and microprocessors has miniaturized the size of the computing aspect to the point where ubiquitous computing (ubicomp) has become possible, but sensors, output devices, data storage, and power supplies have a lot of catching up to do. It is precisely in this domain—the coupling of computation to the physical world—that micromachining will make its biggest contribution yet. To appreciate how to program memory embedded in MEMS with powerful top-down algorithms or simpler bottom-up learning routines, we will now look at how brains in nature work and consider the latest developments in AI, complexity theory, and artificial life.

The human brain and senses, just like nature's manufacturing methods, evolved in a biological context and are concerned mainly with survival and reproduction. Computing needs in MEMS are different, so we do not want to blindly mimic the brain but study it to learn and adapt strategies that fit our needs.

From Neurons to a Brain

It is important to realize that in nature, the simplest forms of life already exhibit complex reflexive behavior without any nerve cells or a brain at all. Even nature's reflexive behavior is often more complex than what even our "smart" robots can do today. Thus, the topic deserves some attention. A very simple brainless and nerveless organism, such as a paramecium, moves toward food or a comfortable temperature zone, orients itself in gravitational and centrifugal fields, responds to sound waves, swims upstream in a water current and toward a cathode at low applied currents and toward the anode at higher currents, moves away from damaging UV radiation and away from a touch and unfamiliar chemicals. Insects with only a few hundred thousand neurons also manage to fly around in real time and manage to avoid obstacles, although their computers are immensely slow, so they obviously must be able to manage their intelligence in some other ways than our large computers do.

In biology, nerve cells connect sense organs to the brain, and the brain processes incoming signals into perceptions. Nerve cells also run the other way—from the brain to the sense organs, enabling the brain to fine-tune its senses to pick up whatever it considers most important; in other words, perception is a two-way street. The brain itself relies on 10^{10} interconnected neurons (Figure 9.37) in 3.5 pounds or 15 cm^3 of gray matter. These neurons act like armies of switches, interconnected at 10^{14} synapses and collectively firing 10^{16} times a second while consuming less power than an ordinary light bulb, making today's attempts at artificial neural networks (see below) a pale version of their natural counterpart. An individual nerve cell does not posses a smidgen of intelligence; the latter emerges only from the interaction of billions of nerve cells. Nerve cells form long, thin fibers that carry electrical signals. The signals involve ions, not free electrons. The ions do not travel along the nerve cell but across its cell membrane. Electrical activity at one position along the nerve triggers activity in the next position. A charge pulse travels along the axon of a neuron (Figure 9.37) at a speed of 300 feet per second (200 miles per hour). This is slow compared with the speed of an electrical pulse in a wire and a million times slower than that in a Si-based switch (milliseconds versus nanoseconds).[59] Nature obviously does not get its advantage from speed; people are not able to learn, and later remember, more than about 2 bits per second for any extended period. If you could maintain that rate for 12 h every day for 100 years, the total would be about three billion bits–less than what we can store today on a regular 5-in. compact disc (CD).[60] The merits of our brain stem from its 3D nature and interconnections of neurons, as well as their individual complexity. The number advantage of human brains might disappear soon enough. As depicted in Volume II, Figure 2.1, the total number of transistors on a 2D chip will reach the number of neurons in the human brain by the year 2010; computers, some predict, will achieve parity in memory capacity with the human brain shortly after (in Volume II, Figure 2.1, the year 2020 is projected for this event).[61] The area density of the neurons was actually surpassed in the mid-1980s.[62] Neurons are not limited to communicating in an on/off or fire/no-fire mode; they send information in the form of rate of firing, a myriad complicated mechanisms increase or decrease signal strengths at synapses, neurons constantly adapt and change (growth and movement of axons and dendrites), and the brain does not employ a single generic neuron.[59] So not only does nature have an advantage in total number of interconnected switches, the switching behavior of a neuron is also significantly more complex than that of a computer switch.

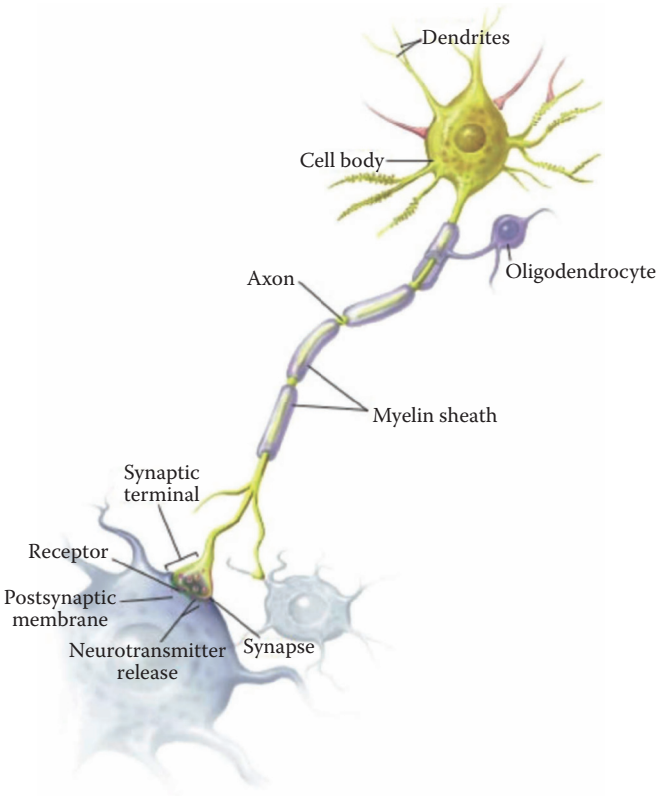

FIGURE 9.37 A neuron cell.

DNA constitutes the long-term read-only memory storage at the heart of life as it evolved on planet earth. A DNA strand with about 2×10^8 nucleotides is tightly packed into a volume of 500 μm^3 (see Figure 4.1). With the assumption that a set of three nucleotides is analogous to a byte, this corresponds to a memory volume density of 1.2 $Mb/\mu m^3$ and about 1 $Kb/\mu m$ in linear density, indicating that memory chips based on DNA as the active elements could have extremely high density. Transcription, or the process of reading

the DNA code, base by base, to make proteins, was illustrated in Figure 2.12. Both the packing density and the transcription process are perfect illustrations of the power of nanochemistry at work in nature. The evolutionary development of brains is very slow, though, and that of *Homo sapiens*—evolution's crown jewel (despite Howard Stern and Rush Limbaugh)—emerged only tens of thousands of years ago. According to Kurzweil's law of accelerating returns (Volume II, Chapter 2), the next salient events (e.g., "intelligent machines making other intelligent machines") will emerge much faster than mutations in our DNA can accommodate. For these next salient events, nature's DNA process is too slow: human intelligence has taken over already, and technological innovations will accumulate faster and faster.

DNA computing utilizes the information coding sequence of DNA and the interactions between complimentary strands to perform complex computations. DNA computing was first demonstrated by Adleman of the University of Southern California, in 1994.[63] The computation in Adleman's experiment ran along at 1014 operations per second, a rate of 100 teraflops, or 100 trillion floating point operations per second. Contrast this with the world's fastest supercomputer, NEC's Earth Simulator, running at just 35.8 teraflops. Obviously, computing with DNA has some advantages over current machines. Whereas today's computing technology rests on a highly linear principle of logic and one computation must be completed before the next can begin, the use of DNA means that an enormous number of calculations can take place simultaneously: the largest supercomputers have a few hundred processors run in parallel, but in some first DNA experiments there were 1 trillion processes running in parallel. This parallel power is many times faster than that of traditional machines—a mix of 1,018 strands of DNA could operate at 10,000 times the speed of today's advanced supercomputers.

In such a computer, the hardware consists of enzymes (restriction nuclease and ligase), a double strand of DNA as input data, and a few short DNA molecules as transition rules or software. The solutions come as pieces of DNA that must be isolated to be read. The process uses only one-ten-billionth of a watt versus tens of watts for an electronic microprocessor. There are some very serious limitations though. Although DNA can store a trillion times more information than current storage media, the way in which the information is processed necessitates a massive amount of DNA if larger-scale problems are to be solved. Furthermore, although the computation process takes place at an awesome speed, the "printout" of the result is excruciatingly sluggish, and involves many steps—it took Adleman a week of laboratory work to extract the potential solutions from his DNA cocktail.

Artificial Intelligence

Two Contenders: Top-Down and Bottom-Up

Introduction

Artificial intelligence is the field of research that attempts to embed intelligence into machines; it includes knowledge-based systems, pattern recognition, automatic learning, natural-language understanding, robotics, etc. Two distinct camps within the AI community today are the very ambitious and traditional, analytical top-down approach and the more modest, natural bottom-up approach. It is interesting to note that the same top-down and bottom-up duality showed up in manufacturing a couple of decades later. Traditionalists represent a rational approach to AI, building intelligence from logical first principles and complex algorithms. Research fields influencing this approach are semiconductor technology, cognitive psychology, and information science. Intelligence has proved very difficult (perhaps too difficult) to describe this way, and although the naturalist approach represents a lower level of computing, it has recently been more successful than traditional AI. Nature-inspired AI emphasizes neural network computing, complex system interactions, and self-organization. The natural approach to AI draws from research such as neuroscience, complex adaptive systems, and molecular biology. As in many research fields, rational statements about the relative merits of these two approaches are hard to find. Comparisons are based not so much on proven scientific facts as on the

powerful egos, reputations of their institutions, and the old-boy networks propagating their views and influencing government funding agencies; the latter often listen only to the "loudest" voice. From the status of the two contending approaches discussed below, it appears that the natural AI approach has been the more successful. The two AI camps are compared in Table 9.10.

Traditional AI

Traditional AI got its unofficial baptism in 1956 at a small conference in Dartmouth, New Hampshire. Present at the time were luminaries such as Marvin Minsky, John McCarthy, and Edward Feigenbaum, and although they were, as many visionary scientists tend to be, over-the-top optimistic, the fruits of AI are now being realized.[59] An example of the optimism reigning in the early days of AI was the prediction about the early successful realization of the Turing test. Alan Turing, mathematician and computer scientist, had predicted, in a 1950 paper, that by the year 2000 a human judge interviewing a computer and a human foil, both hidden from view, would not be able to differentiate the computer from the human when questioning both via a terminal. Although this has not yet materialized, Ray Kurzweil maintains that Turing was correct and might simply be off by about twenty years.[61]

Surprisingly, breakthroughs in AI did not come from software programs reasoning in a precise, highly ordered, step-by-step fashion, as the logicist originators of AI had predicted but from simpler, so-called *expert systems* that made headway in the early 1980s. The latter sort of AI represents a rather practical or heuristic approach to addressing questions in very specific fields, such as the stock market, geophysics, or diagnosis of trouble with humans or cars. These simpler programs rely on rules learned by experience or training fed into the computer. An expert system will typically have a large number of *if-then* rules, and because the computer can quickly analyze thousands of these rules, it can outperform its human experts easily in more and more fields. One prominent example of AI's accomplishments is IBM's Deep Thought computer. Deep Thought beat grand chess master Brent Larsen in 1988 and sailed past world champion Garry Kasparov in May 1997.[59] The chess program has a human-like ability to zero in on a few most promising pattern of moves but does not really have a deep understanding of chess strategy. This makes it more akin to the natural AI approach we review next. Another example is the huge data and rule base of Lenat's Cyc 9 (*Cyc* from *encyclopedia*).[59] Besides information, Cyc again incorporates many rules; half of its memory content is facts, the other half is rules. The highly touted, ten-year-long Japanese Fifth Generation Project, a program from the 1980s meant to catch Japan up with the United States in software development and based on traditional AI, is widely seen as a failure now. The logical and heuristic approach simply proved to be inadequate. Interestingly, the Sixth Generation Project, also known as the Real-World Computing Project, started in Japan in 1992, aimed to achieve human-brain-like computing capabilities by the year 2002. Also this milestone was not met. Clearly, natural AI is today a more favored approach than traditional AI.

Table 9.10 Two Directions in Artificial Intelligence (AI) Research

AI	**Traditional**	Semiconductor technology Information sciences Cognitive psychology
	Reductionist	
	Analytical	
	Top-down (see nanomachining)	
	e.g., rule-based expert systems	
	Natural	Molecular biology Neurosciences Complex adaptive systems
	Complex interactions	
	Bottom-up (see nanochemistry)	
	Self-organization	
	e.g., neural networks	

Marvin Minsky remains a strong proponent of the traditional approach to AI, and in *The Society of Mind* he tries to put the field back on track.[64] In a typical broadside against the bottom-up school, Minsky says, "Why bother building a robot that's capable of getting from here to there, if one gets there it can't tell the difference between a table and a cup of coffee?"[65] The book proposes that one should take multiple approaches to solving a problem. Lenat's Cyc, he claims, does not have enough different approaches, and neural networks are just too dumb.

Natural AI

In the early 1980s, some scientists recognized that traditional AI had been trying to solve problems too much from a top-down mode, whereas a bottoms-up mode might be more appropriate. The very complex programs of traditional AI had not been adapting to or learning from the world around them, an innate capability of even the simplest animals. As in manufacturing today, it appeared that nature might provide some guidance. Neuroscientists speculated that the processing of conscious information takes up as little as a thousandth of the human brain's power and that most of the rest goes into lower-level aspects of survival.[61] In other words, there are deep connections between the need to get food and mate (i.e., survival) and intelligence. It is not so surprising, then, that *Homo sapiens'* DNA is 98.6% the same as that of the lowland gorilla and 97.8% the same as that of the orangutan. On the basis of these observations, the neuroscientist Wilson introduced the concept of creating computer simulations or even simple robots that could avoid danger, find food, and deal in general with a more or less complex environment.[66] Wilson called his computer simulations *animats*. Brooks and coworkers at MIT have been implementing similar ideas into a series of small robots that interact and learn from their environment rather than being loaded up front with a blueprint of every possible scenario the robots might encounter. Sensor data from these robots are shared with all of the different microprocessors on the machines. Maes and coworkers enhanced this type of thinking by adding programs that enable the robot to learn from its mistakes by implementing "positive" and "negative" feedback as well as attempting programs for "motivation," such as "aggression," "curiosity," and "hunger."[66] Brooks's robots are a far cry from von Neumann's self-replicating robots but probably closer to what we can expect to accomplish in this decade with smart MEMS.

Complexity Theory

The science of complexity is preoccupied with the investigation of emergent, self-organizing properties in complex systems. The term *emergent* is used for phenomena in which the whole is greater than the sum of the parts; the whole system exhibits collective behavior that seems not to be built into the individual components in an obvious or explicit manner. In Chapter 3 we saw how Ilya Prigogine with his theory of "dissipative structures" was the first to describe, in a rigid mathematical framework, the coexistence of structure and change, balance and flow, stillness and motion, stability and instability, order and disorder, equilibrium and nonequilibrium, and being and becoming characterizing complex systems.[67] The name *dissipative structures* conveys the notion of dissipation on the one hand and order or structure on the other. Prigogine's monumental and revealing theory is exemplified by living organisms maintaining themselves in a stable state far from equilibrium despite continual flow of matter and energy (metabolism) through their system. Systems far from equilibrium cannot be described by classical thermodynamics, which applies only to systems close to equilibrium. The linear mathematics applicable for small flows (also called *fluxes*) characteristic of systems close to equilibrium must be replaced by nonlinear expressions describing the large fluxes associated with nonequilibrium systems. Dissipative structures do not tend toward equilibrium; on the contrary, they exhibit instabilities, bifurcation points, leading to new forms of order that move the system farther and farther away from the equilibrium state with an accompanying increase in complexity. The greater the complexity, the higher the degree of nonlinearity. The behavior of such a nonequilibrium system cannot be described from the individual parts; instead it behaves as an interconnected whole with multiple feedback loops. Nonlinear equations describing dissipative systems usually have more than one

solution, and as a consequence, new situations may emerge at any moment. This contrasts with classical thermodynamics, where a system is completely predictable and pinned down by one solution only. From Prigogine we learn that the solution or path taken at an instability or bifurcation point in a dissipative structure depends on the previous history of the system and that its behavior is no longer universal but quite unique to the individual system itself. Moving away from equilibrium, we thus move away from the universal to the unique, from determinacy to indeterminacy, from individual components to an interconnected structure with links between structure and its history and a richness and variety as embodied by life itself.[68] Indeterminacy in dissipative structures is also introduced through small random variations, that is, "noise" from the environment. At bifurcation points, the path taken depends very sensitively on such noise, and the outcome becomes even more unpredictable, with new structures and higher order and complexity emerging spontaneously.

That order increases at bifurcation points does not contradict the second law of thermodynamics, as the increased order comes at the expense of greater disorder of the environment. Contrary to our intuition, chaotic systems are highly organized, exhibiting complex patterns dividing and subdividing again and again at smaller and smaller scales. In fluidic instabilities, turbulence will appear at sufficiently large velocities. In the case of chemical reactions, instabilities appear through repeated self-amplifying feedback. In both cases, self-organization, the spontaneous emergence of order, results from the combined effects of nonequilibrium, irreversibility, feedback loops, and instability. In fluidics, an example is the bathtub vortex, and in chemistry, examples include the so-called *chemical clocks* and *catalytic networks of enzymes*. The latter were shown to not only self-organize but also self-reproduce and evolve (see Chapter 3). In physics, an example is laser light, in which, under special circumstances, far from equilibrium and by "pumping" in energy from the outside, coherence spontaneously emerges from incoherent light. The most spectacular example of a self-organizing systems is the earth itself, as detailed in Lovelock and Margulis' Gaia theory.[69] Although often under attack, this theory is gaining more acceptance.

The reductionist approach of traditional AI fails when problems become extremely complex, and often no understanding is gained by breaking them down into their component parts. Earlier we saw how individual neurons or nerve cells work; not one exhibits any intelligence by itself, but intelligence in our brain emerges as a consequence of the interactions of billions of them. This is true for chemical and biological interactions that go on in living organisms, social structures, the weather, the economy, etc. Life itself, according to Kauffman, is nothing but an emergent property of a certain kind of complex system.[70] Although complexity theory seems to have made impact on market prediction, its impact on understanding life and evolution is still a matter of debate; this debate will probably go on for some time (see also Volume I, Chapter 7). Whereas natural AI is already useful in designing smart MEMS, complexity theory will start becoming important only when we work in the nanodomain and deal with self-organizing molecular systems.

Artificial Life

Artificial life, or a-life, is the study of lifelike creatures built by humans. This new science was officially inaugurated in Los Alamos, New Mexico, at a 1987 gathering organized by Christopher G. Langton.[66] Computer-generated entities or cellular automata behaving as self-operating machines, processing information about their surroundings, proceeding logically, and replicating themselves, were already predicted by the legendary mathematician von Neumann in the late 1940s. Today, many creatures of this type—really nothing more than software code—have been demonstrated, even on laptop computers. Some practitioners believe that by watching these creatures evolve on the computer screen and subjecting them to a variety of stresses, we can learn important lessons about the evolution of real-life systems more quickly and less expensively than with standard experimentation. Early a-life programs include *Boids* (http://www.lifeartificial.info/flocking-boid-behavior), which exhibit flocking behavior uncannily similar to that of real birds. The simple rules in this program control only individual Boids,

but somehow flocking group behavior emerges (see complexity theory).[71] *Network Tierra* by Thomas Ray features software simulations of organisms—*creatures* in which each *cell* has its own DNA-like genetic code.[71] *Tierra* can be downloaded from http://www.hip.atr.co.jp/~ray/tierra/tierra.html. *Tierra* organisms, in their simulated world, compete for a limited resource (energy) provided by the computer CPU. The seed electronic organism, the Ancestor in *Tierra*, has only three genes, and besides feeding it is designed to replicate itself and to mutate. Several sources of mutations are programmed in. There is also a *reaper* that kills off creatures that are less well adapted and those that are too old. To everyone's surprise, *Tierra* very quickly developed some lifelike evolution characteristics, such as the development of new species, parasites, defense mechanisms against parasites, symbiotic relationships, competition for food, and even something akin to punctuated equilibrium as proposed by Gould and Eldredge in 1972.[70] The discussion about how increasing complexity arose is an ongoing one. In the case of *Tierra*, there was no tendency toward increasing complexity; on the contrary, simpler creatures evolved over time. Emergence of complexity is a fact of life, though, and Ray is trying to induce it in *Network Tierra*. For evolution to proceed in this artificial world, it has become clear that a lifelike complexity must challenge the organisms. Ray is doing this now by letting his organisms grow on the Internet with its diverse electronic life. The organism, like a screensaver, becomes active only when the host computer is inactive. Ray speculates on the emergence of such intelligent life in *Tierra*-like environments; it will make the Turing test irrelevant. For interested readers, more on artificial life can be found at Avida Artificial Life Group (http://www.krl.caltech.edu/avida), Boids (http://hmt.com/cwr/boids.html), Complexity On-Line (http://www.csu.edu.au/complex), Dawkins (http://www.spacelab.net/~catalj), Primordial Soup Kitchen (http://www.psoup.math.wisc.edu/kitchen.html), Stuart Kauffman (http://www.santafe.edu.edu/People/kauffman), Swarm (http://www.santafe.edu/projects/swarm), and *Tierra* (http://www.hip.atr.co.jp/~ray/tierra/tierra.html). As in the case of complexity theory, artificial life is bound to become more important as we move from MEMS to NEMS.

Artificial Neural Network Software

As we have seen, neurons, to a first-order approximation, work by gathering signals from other neurons, weighing each by varying algebraic amounts, and then internally summing all the inputs. If this cumulative signal exceeds some internally stored threshold value, the neuron fires its own signal that is subsequently gathered in by other downstream neurons. John Hopfield, in 1982, invented a simple mathematical model of a network of nerve cells, called a *neural net*. As a quantum physicist Hopfield asked himself if a neuron in a brain might not act like an atom in a lattice. He reasoned that like an atom can take on discrete states, a neuron might also be found in discrete states: it can fire or not fire. His idea boiled down to the simple idea that just as atoms in a crystal arrange themselves to minimize the energy, so must a neural network minimize its "energy." This led to his celebrated 1982 paper, "Neural Networks and Physical Systems with Emergent Collective Computational Abilities." He showed that if many neural units were hooked together, they acquired computational abilities. The artificial neuron is a mathematical construct that emulates the more salient functions of biological neurons, i.e., the signal integration and threshold firing behavior. The most basic neural software consists of a layer of input and output *nodes*. When the input nodes receive a strong enough signal they "fire," sending their own signals to the output nodes attached to them. The input nodes in such a simple system represent an array of input stimuli, and a response is picked up from the output nodes. To make the neural network produce the right answer, an outside controller, usually a human or a computer programmed with the correct database, must adjust the switches between the input and output till the output produces the right answer. In neural network jargon, these settings are called *weights*. In the simplest case, we make the weights either one or zero; in general, though we set the weights to any of a range of signal pass-through strengths. Increasing the weight between an input and output node means that the input node signal will make a larger contribution to the likelihood that the connected output node will fire. This corresponds to an

excitatory signal in a nerve cell. A decrease in weight corresponds to an inhibitory signal and can stop a branch in the net from cascading throughout the net or shut off a nerve cell in the biological equivalent. The intelligence within the neural network is stored within these sundry algebraic connection weights. The process of teaching the network the appropriate weights is a complicated and often lengthy process. Frank Rosenblatt designed the first neural network—a so-called *perceptron*—that could be trained by consecutive small adaptations of the weighing factors.[59] This was achieved by comparing the results of consecutive network attempts at the right answer with the desired results and making small changes to the weighing factors after each comparison; more dramatic adjustments would have wiped out all previous training and give the wrong answers for any other pattern recognition.

Using a Hopfield-style neural net, Sahley and Gelperin worked out a model that faithfully captured the learning a common garden slug (*Limax maximus*) displayed when confronted with smells such as that of quinine (which it dislikes) and carrots (which it likes).[70] Their model neural net is shown in Figure 9.38.

Neural nets have been used in sensor array applications such as artificial noses and tongues.[72] In these instruments, a small number of odor and taste sensors are trained to smell and taste food and drinks containing hundreds of different chemicals. Making selective sensors for each separate chemical would be impossible, but a limited sensor array develops specific patterns (fingerprints) for complex chemical mixtures that correlate well with the human sensory evaluation. This approach has taken a rap for being a "black box"—it gives the right results but does not explain why. Indeed, neural net software packages develop connection traces internally that embody the rules behind the conceptual space on which they are training. For many chemical and biological applications, however, it is not important to know the identity of the individual components of a complex mixture, but it is important to sound an alarm if an unusual pattern is detected; for this application, natural AI seems the appropriate way to embed intelligence.

Questions

9.1: What is meant by bottom-up and top-down artificial intelligence approaches? Which approach makes most sense for the development of smart MEMS?

9.2: Compare the function of a set of neurons in the brain with an artificial neural net. Find some real-life examples where neural nets are used today.

9.3: Explain how μ-3D batteries are better than thin-film batteries for powering a MEMS device.

9.4: Sketch a rough Ragone plot for capacitors, supercapacitors, batteries and fuel cells.

9.5: What MEMS power would you put into a microrobot? A microrocket? A microsubmarine? A microbutterfly?

9.6: Discuss some options for hydrogen storage. Why is it so important for the future of fuel cells?

9.7: As far as fuel cells are concerned what is the merit of biofuel cells?

9.8: Explain for what uses you might prefer a supercapacitor over a Li-ion battery.

9.9: What is the role of a bipolar plate in a fuel cell? How could C-MEMS make for better bipolar plates?

9.10: What are some of the promises and challenges involved with building micromachined combustion engines?

9.11: In what ways can MEMS and NEMS improve solar cells?

9.12: Explain with a diagram how a Grätzel solar cell works.

9.13: What are the fundamental limits in computing power? Use equations.

9.14: Explain how a fractal design of the electrodes might benefit a fuel cell.

9.15: Explain the scaling behavior of a cube and a sheet in terms of resistance and surface to volume ratio.

Introduction to Part III

Chapter 10 MEMS and NEMS Applications

Introduction to Part III

In Chapter 10 on MEMS and NEMS applications we cover the market dynamics for MEMS and NEMS commercial products. We cover both lithography- and nonlithography-based MEMS. After an analysis of the total world market in MEMS, we consider some selected market categories, i.e., MEMS in the automotive market; MEMS in medical and biotechnology markets (bio-MEMS); MEMS in industrial automation, including environmental monitoring markets; and MEMS in information technology peripherals and telecommunications markets.

The market expectations for NEMS today are much greater than they ever were for MEMS. An important objective in the section on nanotechnology markets is to try to help the reader distinguish between hype and science/facts, perhaps helping to avoid yet another lurking technology bubble.

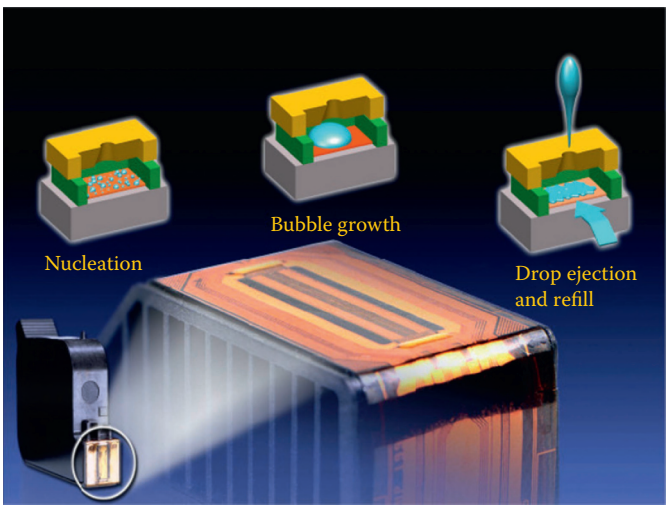
Picture of packaged digital micromirror devices (DMD™) from Texas Instruments (TI). These are pixel devices; shown are the VGA (640 × 480), the SVGA (800 × 600), and the XGA (1024 × 768). Digital mirror devices constitute the largest microelectromechanical system (MEMS) product after read-write heads and ink-jet heads.



Another major microelectromechanical system (MEMS) application: an ink-jet printer head. These represent the second largest MEMS market, after read-write heads.

Michael Riordan and Lillian Hoddeson, Crystal Fire (W. W. Norton, 1998)

People will work every bit as hard to fool themselves as they will to fool others—which makes it very difficult to tell just where the line between foolishness and fraud is located.

Robert Park
Voodoo Science (Oxford University Press, 2000)

Introduction

The field of microelectromechanical systems (MEMS) and nanoelectromechanical systems (NEMS) is currently undergoing a total makeover. Mechanical and optical MEMS (MOEMS) products have made the transition out of the laboratory and into the marketplace with a plethora of new products, including a strong entry into the consumer electronics field (mobile phones, cameras, laptop computers, games, etc.). Biological MEMS (bio-MEMS), on the other hand, is in the doldrums, with little commercial acceptance, while NEMS, especially BIONEMS, is stealing all the research dollars. In commercial terms, if MEMS is entering adolescence, the word *nano* still seems to derive from a verb that means "to seek and get venture capital funding" instead of from the Greek noun for dwarf. Today the market dynamics for MEMS and NEMS commercial products are very different, and we treat MEMS and NEMS applications separately.

We start with a preamble about today's MEMS market character and the current and future position of the United States in MEMS and NEMS in general. We are interested in both lithography-based and non-lithography-based MEMS. Compared with lithography-based MEMS, thenon-lithography MEMS approach is underreported, and it is especially in

the latter area that progress in the United States is lacking.

To understand where revenues in MEMS are derived from, and to appreciate where further growth can be expected from, we provide definitions of MEMS, bio-MEMS, microsystems technology (MST), micrototal analysis system (μ-TAS), lab-on-a-chip (LOC), micromechatronics, miniature sensors and actuators, microstructures or microcomponents, and first-level packaged MEMS/MST and the smallest commercialized unit. These terms are familiar to micromachinists but are sometimes confused in marketing reports. An evaluation of MEMS applications better describing the MEMS contribution to the final product and the manufacturing method used to produce the MEMS [e.g., non-lithography-based, such as computer numerical control (CNC) machined, or fabricated using a lithography-based technique, such as LIGA] might be of help in interpreting market studies that are often vague about what the term *microfabricated products* comprises. Companies and research organizations interested in entering the field might then at least be able to judge, based on the underlying study, whether they have the manufacturing expertise or know-how to make them possible contenders.

After an analysis of the total world market in MEMS, we consider some selected market categories, i.e., MEMS in the automotive market; MEMS in medical and biotechnology markets (bio-MEMS); MEMS in industrial automation, including environmental monitoring markets; and MEMS in information technology (IT) peripherals and telecommunications markets.

The market expectations for nanotechnology today are much greater than they ever were for MEMS. An important objective in the section on nanotechnology markets is to try to help the reader distinguish between hype and factual science, perhaps helping to avoid yet another lurking technology bubble.

As highlighted in Chapter 1, which compares traditional manufacturing and MEMS and NEMS, we hope that a better understanding of how to match different manufacturing options with a given application will guide the identification of additional killer MEMS and NEMS applications and encourage more companies and research organizations to innovate faster based on their in-house manufacturing tools and know-how.

Preamble on the MEMS Market

Lithography-Based MEMS

Lithography-based MEMS defines all micromanufacturing involving a lithography step. It was not too long ago that lithography-based MEMS was surrounded with a similar hype that surrounds NEMS today. It was said that MEMS, by using highly automated, parallel-manufacturing techniques, would enjoy the same economy of scale as integrated circuits (ICs) and ride similar cost curves. Using "micromachining" technology (much of it borrowed from the IC industry), pumps, sensors, relays, motors—just about any manufactured gizmo in our daily world—would be shrunk down to the micrometer scale, so that it might be hidden, worn, or implanted and in some cases be inexpensive enough for a disposable application. In those early years of MEMS (the early 1980s), when MEMS was almost 100% silicon-based, it was even projected that long before 2008, its market would be larger than that for ICs. This notion was based on the expectation of many more applications for MEMS and combinations of MEMS and ICs than for ICs alone. This market prediction has not been fulfilled yet: the 2006 worldwide IC market was $211.0 billion (see also Volume I, Appendix 1B); in contrast, the worldwide MEMS market for the same year was estimated between $6.3 and $16.5 billion (depending on which criteria one uses to define MEMS). In other words, after more than twenty years, one could claim a MEMS market of at most 8% of the total IC market, taking into account that this was achieved only by changing the criteria about what qualified as MEMS [e.g., including nonsilicon devices, such as thin-film read-write (RW) heads]. The MEMS market in 2007 consisted principally of RW heads, ink-jet printer heads, digital light processing chips, pressure sensors, accelerometers, flow sensors, gyroscopes, microphones, oscillators, and radiofrequency (RF) switches, which, except for digital light processing (DLP) chips, all are becoming commodity products very swiftly and

are now more and more manufactured outside the United States (profit margins have become very thin on most of these products). Early market studies did overstate dramatically what impact Si-based MEMS had on the world economy and how fast that would happen. A realistic number for the market of Si-MEMS products today is less than 3% of the IC market (even the $6.3 billion MEMS sales in 2006, i.e., 3% of the $211 billion IC market for 2006, included nonsilicon devices). The main reason that MEMS sales continue to lag behind IC sales has been the relatively stable price-to-performance (p/p) ratio of sensors and actuators ever since 1960, which is in marked contrast to the p/p ratio of ICs, which has fallen enormously between 1960 and 2007 and is now significantly below that for sensors and actuators. As a consequence of these changes, the cost of a measurement system is, in general, dominated first by the cost of the microactuator and second by the cost of the microsensor.

When including nonsilicon MEMS (which many market studies now do), and especially when also counting non-lithography-based MEMS (e.g., precision-engineered products; see below) (which very few market studies do) MEMS might constitute 10% of all current IC sales.

If some investors still cringe when they hear MEMS mentioned, they might be remembering the 2001 technology bubble around "optical MEMS switches" for telecommunications. Optical channel cross-connecting is a key function in most communication systems. In a *hybrid approach*, one converts optical data streams into electronic data using electronic cross-connection technology. Then, the electronic data streams are converted back into optical signals. In electronic cross-connecting of N-by-N channels ($N \times N$), N may be on the order of thousands. Using arrays of MEMS micromirrors, one can obviate the need for back-and-forth conversion of light to electrical signals. Cross-connecting optical channels directly in the photonic domain is known as *all-optical switching*. These all-optical path switches could, in theory, operate at any wavelength, at any speed, and using any kind of protocol. In 2007, the size of typical commercially available all-optical channel switches may switch between 80 or 128 channels (N = 80 or 128) (see Figure 10.1). But in the late 1990s, all-optical channel cross-connecting switches with N = 1000 were already promised by an army of MOEMS start-up companies (150 worldwide). Unfortunately, the more than $10 billion investment by large telecommunication companies such as Corning, JDF Uniphase, and Nortel in 1999–2000 for those very large arrays of micromirror devices became a textbook example of what former Federal Reserve chairman Alan Greenspan called "irrational exuberance." The all-optical switch mania started in 2000 when Nortel bought up the start-up Xros Inc. for $3.25 billion. By the time Nortel killed off the company in 2002, the market had flooded with competitors, most of them with similar MEMS-based ideas for all-optical switches, and suddenly the 1000-port mania was relegated to the oops file. There were not enough customers for that many start-ups, and

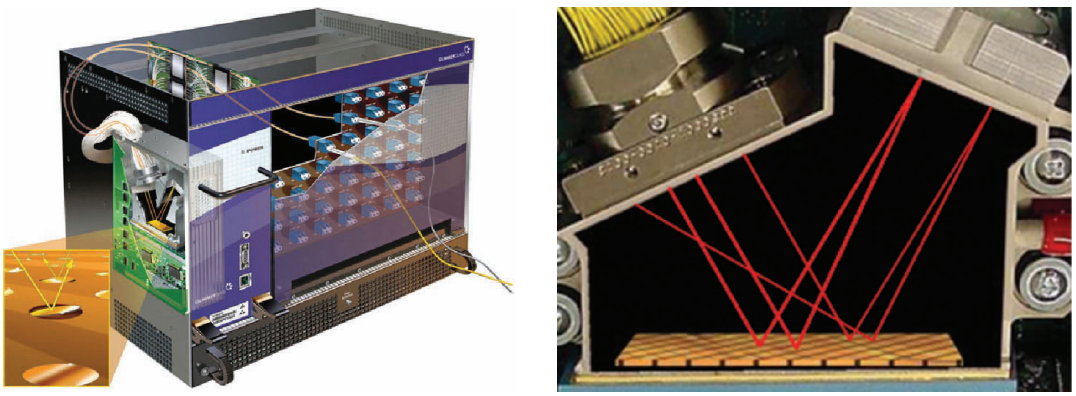

FIGURE 10.1 Glimmerglass Intelligent Optical Switch offers optical to optical switching (http://www.glimmerglass.com/technology.aspx). This switch from Glimmerglass couples light from an input fiber array of up to eighty or more inputs into an output array of the same scale. A microelectromechanical system mirror array directs light from any one input to any of the output fibers. (Images from Glimmerglass.)

the three largest investing companies pulled back, leaving a few individuals very rich, but with neither new jobs nor products to show for their time and with many scientists and engineers out of a job (or working as consultants—often synonymous with jobless in the United States). The rapid growth of the telecommunications industry initially brought great demand for MEMS optical switches. Unfortunately, the expected demand did not meet the actual demand. What was left of the all-optical switching market, in the period between 2002 and 2004, was littered with the broken shells of start-ups that often tried to survive by doing MEMS foundry work. Many of them had never got past the design stage, a few shipped products, and others had nothing to show for but PowerPoint presentations. Surprisingly, even some of the latter managed to cheat investors and large companies out of money as MBAs and scientists alike oversold the technology. The experience embittered many investors, and no wonder.

Today, some surviving MOEMS companies, building all-optical switches, are successfully targeting more modest switch applications; say for apartment buildings or university switchboards and for new emerging applications, such as semiconductor test equipment. Companies such as Glimmerglass claim to have solved the problems previously associated with the MOEMS switches and maintain that their optical switches are more reliable, less complicated, and more cost-effective. The Glimmerglass switch, shown in Figure 10.1, is an 80 × 80 (input × output fibers) switch with promising sales figures. A big challenge for this new generation of optical-switch vendors is overcoming the negative perceptions left over from the boom years.

Instead of switching signals among very large arrays of fiber optic cables for telecommunication switches, Texas Instruments (TI) targeted its digital light processing (DLP) technology to projectors and video displays. Because it focused on the right mass consumer application from the get-go, TI's digital micromirror device (DMD™) turned out to be a big-scale MEMS success (see Example 10.1 below).

A similar case of "irrational exuberance," although on a much smaller scale, played out with the early investments in microfluidics for high-throughput analysis for new drug candidates [called *high-throughput screening* (HTS)] and for high-throughput analysis in diagnostics (Figure 10.2). Early investments for these application came mostly from cash-rich drug companies and huge diagnostic firms, to help them with faster discovery of new drugs and faster diagnostics, respectively, but there was no market beyond some research equipment, and again, too many competitors chased too few customers.

Microfluidic applications in point-of-care (POC) diagnostics—a mass-market application—appear more promising. In diagnostics, one often deals

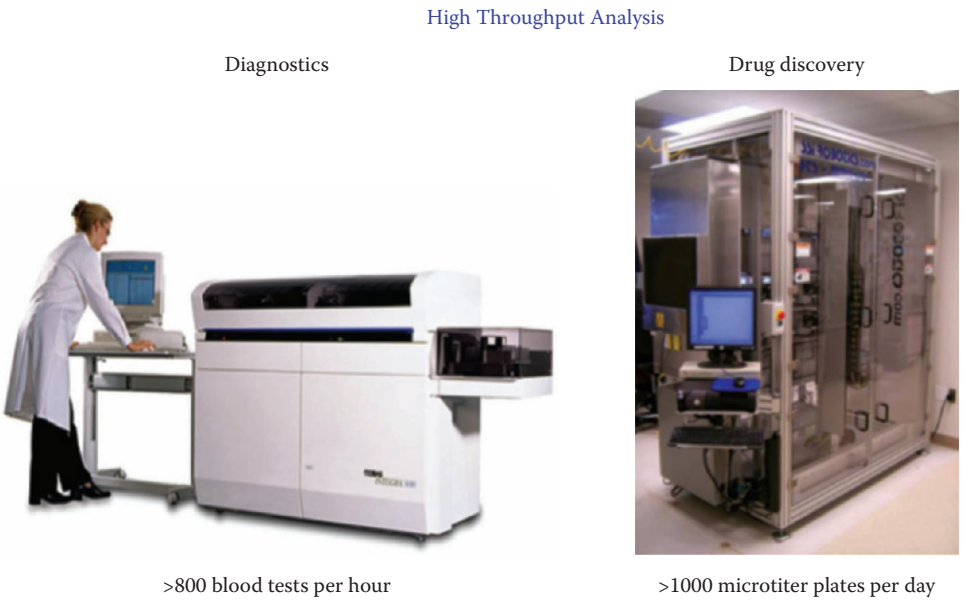

FIGURE 10.2 High-throughput analysis in diagnostics and high-throughput screening in drug discovery.

with disposable products of considerable size compared with a typical IC, and one must compete with traditional products made in huge batches on paper or plastic substrates or even in roll-to-roll (R2R) continuous processes (say, glucose sensor paper strips and aspirin pills). This leaves little room for batch-type Si technology, and as a consequence, most new biotechnology-related MEMS products are nonsilicon-based. Although it failed for HTS applications, nonsilicon microfluidics is poised to succeed in diagnostic applications. This parallels the case of micromirrors that failed for very large communication switches (expensive product/small market) but succeeded for portable projectors (less expensive product/huge market; see next section).

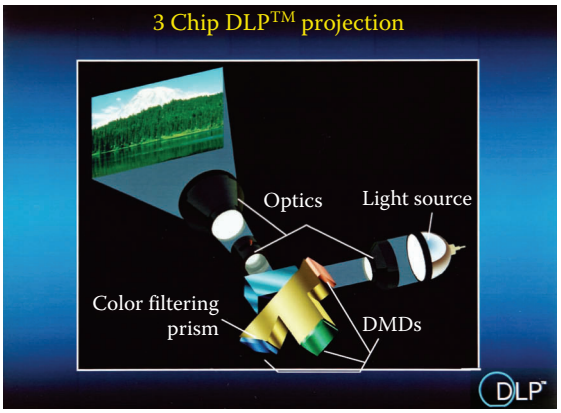

FIGURE 10.3 Texas Instruments DMDs. Digital light processing replaces three conventional LCDs with one to three DMDs, one each for the red, green, and blue components of a video image. Each chip contains approximately 750,000 or more microscopic mirrors or pixels. A single light source (bulb) drives all DMDs, the monochromatic images are converged internally using a prism system, and the resulting full-color image is projected via a lens onto a screen. DLP projectors are lightweight, relatively bright, and simple to set up and operate, and they provide a much better contrast range and higher resolution than LCD projectors. The DLP technology is more expensive at present than LCD.

Example 10.1: Texas Instruments Digital Micromirror Devices

An example of a successful MOEMS application comes from the optical switching arena with the DLP chip from TI. DMDs, invented in 1987 by TI's Larry Hornbeck, consist of an array of hundreds of thousands (from 480,000 to >2,000,000) of electrically actuated micromirrors built as a superstructure over complementary metal-oxide-silicon (CMOS) address circuitry. Two pixels are schematically illustrated in Volume II, Figure 7.98, together with the underlying Si chip and circuitry. Each pixel is made up of a reflective aluminum micromirror supported from a central post. The manufacture of this chip illustrates the integration of a nonsilicon MEMS with a CMOS SRAM 8-inch wafer process line. The surface micromachining process to fabricate DMDs on wafers incorporating SRAM CMOS electronic address and control circuitry is illustrated in Volume II, Figure 7.100. The aluminum alloy DMDs are used in consumer products such as projectors and digital television (Figure 10.3). For a picture of DMD chips, see the illustration in the heading of this chapter.

Millions of those DMDs have now been built into projectors (the first one came out in 1996 from InFocus) and big-screen televisions (the first came out in 2002 from Samsung) (Figure 10.3). It was projected that by 2009, MEMS displays would become the second largest MEMS market, after thin-film read-write (RW) heads (Nexus). A major advantage for TI is that DLP chips are an exception to the high-volume/low-price rule, typically for all ICs and most MEMS devices: the 2004 asking price for a DLP chip was $400; it was estimated at $190 in 2009 (Nexus).[1] There is little question that DMD is the most complex MEMS in the world, and some at TI are bragging that TI has more moving parts on one wafer than Analog Devices Inc. (ADI) builds accelerometers in a year (ADI ships 2 million units a week).

Mechanical and MOEMS devices have been around since the 1980s, and it appears that this market finally has achieved mass-market acceptance in IT peripherals. A primary reason is the demand for read-write heads, ink-jet heads, and microdisplays. Since about 2004–2005, these MEMS devices have been incorporated in consumer products. Read-write heads used to be mostly used in personal computers (PCs) (a market that has slowed down) but can now be found in mp3 players, smart phones, digital video cameras, set-top players, and DVD recorders. Ink-jet heads are migrating from regular printers to printers of digital photos—especially photos from cell phone cameras—and microdisplays found their way

from projectors and high-definition, large-screen televisions to microdisplays for mobile handsets [e.g., the iMoD (interferometric modulator display), developed at Qualcomm] (see also "MEMS in IT Peripherals and Telecommunications Markets").

The automotive field, also, continues to be a strong market driver for MEMS, especially for security applications, with the demand for pressure sensors, accelerometers, and gyros. For example, the electronic stability program (ESP) and the tire pressure monitoring systems (TPMS) are currently promoting worldwide yet more use of MEMS in the car industry.

Recently, the market for accelerometers in consumer electronics (CE) (computers, games, phones, etc.) has also started to explode. Consumer electronics have the potential to dwarf the automotive application, not only for accelerometers but also for pressure sensors and gyros. Consequently MEMS growth is expected by some to follow a hockey stick curve, with the value of products rising to $40 billion in 2015 and $200 billion in 2025![2] (see also an estimate by Dr. Marinis from Draper Laboratory: http://www.sem.org/PDF/s01p01.pdf). The problem now is one of profitability rather than the absence of real product opportunities: how to earn money on, say, $0.32 microphones or $1.35 triaxis accelerometers for mobile handsets? Only by becoming more similar to the IC industry can MEMS devices achieve this goal, i.e., through more integration on larger (8-inch) Si wafers. In a sense, as far as mechanical and MOEMS are concerned, the IC industry has now swallowed the MEMS field.

Despite two important "bubble busts" in the MEMS market, we do expect that besides a booming MEMS business in consumer electronics, many new MEMS applications are yet to be realized and that MEMS will be essential in facilitating the handshake between the macro and nano worlds. Furthermore, this author speculates that it is in nanotechnology, especially when considering bottom-up manufacturing (nanochemistry), that a paradigm shift away from IC-type manufacturing will take shape, and that nanotechnology holds the potential for having a much larger impact on society than IC technology ever did. The IC industry will then become subservient to this larger nano industry, just as MEMS is subservient to the IC industry today.

Non-Lithography-Based MEMS

In this book, we also cover non-lithography-based miniaturization techniques and their applications. Compared with lithography-based MEMS, this technology area is underreported, as results often are evolutionary rather than revolutionary. Less widely advertised than lithography-based MEMS advances, which are oversold in public relation hungry universities and government institutes, non-lithography micromachining, practiced mostly in highly competitive private companies of the likes of Sankyo Seiki, Samsung, Philips, Olympus, etc., actually leads to more practical products faster than lithography-based MEMS. Applications include computer hard discs, photocopier drums, mold inserts for compact disc reader heads, high-definition TV projection lenses, and VCR scanning heads. Some examples of non-lithography MEMS products are shown in Figure 10.4. The United States is in a rather difficult position when it comes to non-lithography-based MEMS [such as electrical discharge machining (EDM) and CNC]. Below, we discuss some reasons why the United States is losing out in this type of miniaturization.

Over the last twenty years, the United States' MEMS efforts focused on exploiting silicon planar lithography as the core technology for microstructure fabrication, whereas in Japan and Europe, a much wider variety of miniaturization technologies were pursued, including several non-lithography-based MEMS methods. A prominent example of this, reviewed in Volume II, Chapter 6, is the ten-year Micromachine Technology Project [also called the *Desk Top Factory* (DTF)], initiated in Japan in 1991 and focused on both a wide range of fabrication technologies and a wide range of materials, including extensions to more traditional machining processes (Figure 10.5). More recently, Korea and the European Community have started similar efforts. There are no such concentrated efforts going on in the United States[3] at the moment.

In Japan, where MEMS was driven by mechanical engineering, there was also more focus on the fabrication and assembly of discrete products, whereas MEMS in the United States, being driven by the IC industry, viewed such work as

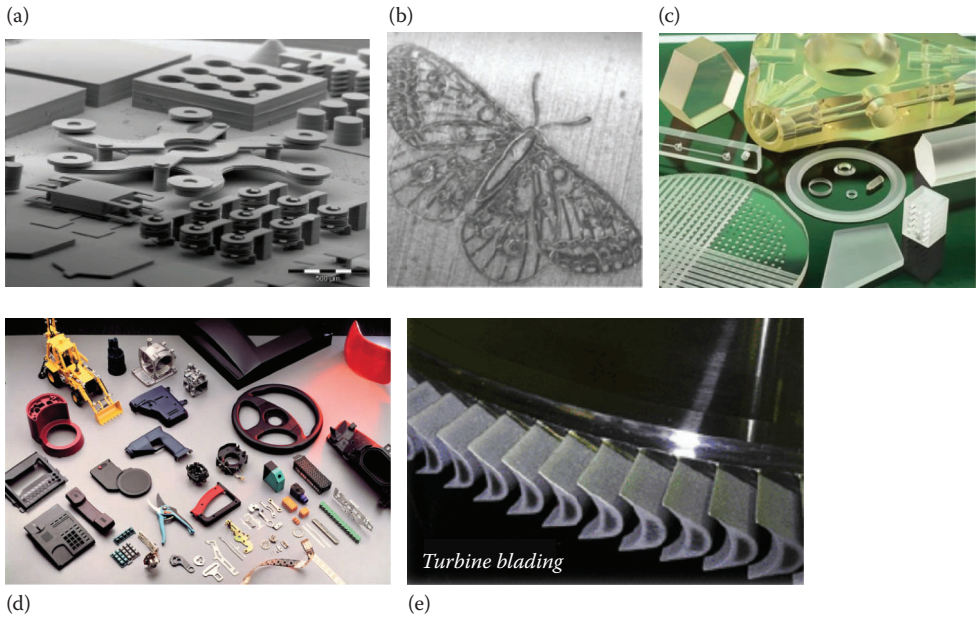

FIGURE 10.4 Examples of nonlithography microelectromechanical system products: products made with precision machining. (a) Electrochemical fabrication (EFAB) is a solid, free-form fabrication technology that can create complex, miniature three-dimensional metal structures that are impossible or impractical to make using other technologies, such as electrical discharge machining (EDM), laser machining, or silicon micromachining. (b) Laser marking and engraving. (c) Precision glass components produced through computer numerical control (CNC) machining, grounding, lapping, and polishing. (d) Electrical discharge-machined products. (e) Turbine blades made with electrochemical machining.

fundamentally violating the paradigm of batch fabrication.[3] Assembly projects are only now gaining vigor in the United States as part of efforts in nanotechnology, embodied, for example, by the Zyvex Nanomanipulator, shown in Figure 10.6 (see also Chapter 4, this volume). The Zyvex Nanomanipulator is able to grab and position objects as small as 10 nm in diameter.

It is difficult to convince U.S. funding agencies to invest in evolutionary-type technology, such as developing better CNC machining tool bits (see Volume II, Chapter 6), but the miniaturization of devices associated with a large number of application fields is today demanding the production of components with manufactured features in the range of a few microns to a few hundred microns, requiring those new tool bits. These fields include optics, electronics, medicine, biotechnology, communications, sensors,

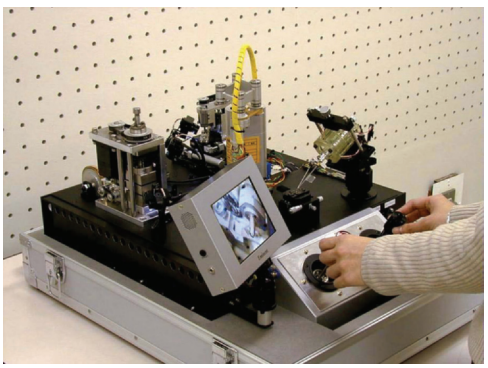

FIGURE 10.5 Example Desk Top Factory (DTF) at AIST (see http://www.dtf.ne.jp/en/achievements.html for other examples).

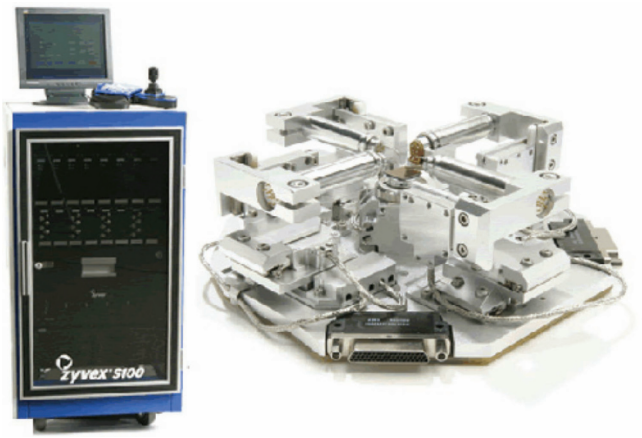

FIGURE 10.6 The S100 Nanomanipulator System from Zyvex is a manipulation and testing tool used with a scanning electron microscope for micro- and nanoscale research, development, and production applications (http://www.zyvex.com).

and avionics, to name just a few. Specific applications are medical implants, diagnostic and remediation devices, microscale batteries and fuel cells, fluidic microchemical reactors requiring microscale pumps, valves and mixing devices, microfluidic systems in general, microholes for fiber optics, micronozzles for high-temperature jets, micromolds and deep x-ray lithography masks, optical lenses, etc. Functional requirements for these applications demand tight tolerances and the use of a wide variety of engineering materials, e.g., steels, titanium, brass, aluminum, platinum, iridium, ceramics, polymers, and composites.

The United States has lost dominance of the tooling industry and the manufacturing skills in many of the precision machining areas needed for the identified applications. The U.S. machine tool industry enjoyed a period of global dominance between the early 1900s and the late 1970s. In the final quarter of the last century, however, almost every major U.S. producer lost domestic market share as a result of import competition. By the early 1990s, several segments of the U.S. machine tool industry appeared poised on the edge of market exit. In a 2007 World Technology Evaluation Center (WTEC) publication, we detailed our observation that countries not manufacturing high-technology goods today are increasingly at a loss, as they do not learn about the newest manufacturing needs from developing the next-generation products.[3]

In the short term, free market forces in a global economy will push mass-product manufacturing of highly accurate miniaturized devices, requiring quality control and multiple assembly steps, toward low-cost, low-wage countries, and the manufacture of small-lot, high-added-value products and items that require intense service assistance will remain in the more developed countries. But the real question is this one: can an advanced country, in the long run, survive without continued input on practical manufacturing, processes, and new materials know-how? The often quoted excuse for exporting manufacturing jobs abroad, usually coming from higher management and MBAs (immune, at least for now, from losing their own jobs), is that the United States and other developed countries will still design, market, and sell those next-generation products. That argument will be rendered wishful thinking, though, when the new materials and processes that go into next-generation products are foreign owned.

MEMS lithography-based and non-lithography-based micromachining will continue to enrich the nations that invest in it most heavily. To stem the hollowing out of the manufacturing base in developed nations, the governments of many countries have made considerable investments in the miniaturization of new products (MEMS and NEMS) and the miniaturization of manufacturing tools (for example, the DTF, mentioned above and detailed in Volume II, Chapter 6). Based on the state-of-the-art and current investment levels (private and government), Europe (especially Germany and Switzerland), and Asia (particularly Japan and Korea) will gain the most from developments in non-lithography-based machining, as they have a long tradition in it and have invested more heavily in this field. As pointed out above, the United States, over the last twenty years, has emphasized lithography-based MEMS with outstanding research results and a dominant market position, but as many MEMS products have become commodity products, Asian countries stand to reap more benefits from them. In more traditional micromanufacturing, the United States is now lagging behind Japan, Germany, Switzerland, and Korea, and as pointed out above, such a lag tends to get worse as time goes on as every new generation of products (from television sets to mobile phones) incorporates some new manufacturing and materials know-how.

If the U.S. government continues to invest in nanotechnology, it will be the United States that will again reap the initial benefits, first in new materials and then in new devices. But to be able to manufacture and gain from those investments in the longer term, it might be wise to start something on the scale of the Manhattan Project in advanced manufacturing techniques; otherwise, the United States will not reap the benefits from its research and development investments itself, as it would no longer be able to implement what it invents.

MEMS Market Studies

As pointed out above, almost all MEMS market projections from before the year 2000 were too optimistic (e.g., $6.3 billion realized vs. a projected more

Table 10.1 From Concept to Full Commercialization

Product	Discovery	Product Development	Cost Reduction	Full Commercialization	Duration (Years)
Pressure sensors	1954–1961	1961–1975 (1961 first prototype at Kulite)	1975–1984	1984	23
Ink-jet printer nozzles	1977 (IBM)	1984–1990	1990–1996	1996	19
Accelerometers	1970 (Kulite piezoresistive)–1979 (Stanford-capacitive)	1985–1990	1990–1995	1995	25 16
Microrelays	1977–1982	1982–1998	1998–2005	2005	28
Photonics/displays	1979 IBM	1986–1998	1998–2005	2001	22
Bio-/chemical sensors	1980–1994	1994–2000	2000–2005	2005	25
Gyros/rate sensors	1982–1990	1990–1996	1996–2004	2004	22
Radiofrequency	1994–1998	1998–2002	2002–2007	2007	13

Source: Grace Associates.

than $200 billion in 2006!). MEMS market studies today have become more judicious, but this author believes that many are still misleading for one or more of the following reasons:

- Many MEMS market studies do not specify whether their market numbers pertain to the MEMS structure alone or whether they include one or more higher system levels. A refreshing change in this regard came from Nexus (http://www.nexus-mems.com) and Yole Développement (http://www.yole.fr), which distinguish in their latest market studies between the first-level packaged MEMS and the smallest commercialized unit. This is illustrated for the case of an ink-jet cartridge in Figure 10.13 (see under Definitions). One cannot buy ink-jet heads alone, and from the point of view of the market (products sold and bought), the smallest commercialized unit is the cartridge or printer head. This decreases the total volume of the market (number of MEMS pieces) but provides a more realistic vision of component-based systems.
- A few market projections still include both MEMS optical switches for telecommunications and MEMS-based microfluidics for high-throughput screening (HTS), despite the fact that both applications have almost disappeared from the commercial scene.
- Most market studies do not specify the machining method used to make the MEMS part. The product could be precision machined, silicon- or non-silicon-based, and involve lithography or not.
- Looking back at the many market reports from the past, it is striking how the development time for a new MEMS product was underestimated over and over again. Table 10.1, based on a report by Grace Associates (http://www.rgrace.com), presents a sobering reality. On average, it still takes about 21 years to go from a new idea to a fully commercialized product. As MEMS products become more integrated and more IC-like, this development time will shrink dramatically.

The lack of more commercially successful applications for micromachines conflicts with the fact that in the evolution of electronic products, miniaturization only follows as a very natural development initiated by a continuing market pull. With radio transceivers, optical pickup systems for compact disc players, hard disks, thin-film read-write (RW) heads, camcorders, etc., features or functions that take up too much space must be compressed; otherwise, they do not survive. Outside the electronics area (such as in automotive sensors and biomedical devices), the market pull is similarly toward miniaturization. So most probably, the real MEMS market has not yet materialized, and product offerings are not meeting the specifications of the market.

There are several reasons why the MEMS market still lags behind the IC market by a factor of 10 or more:

- Micromachining is too often equated with microelectronics, specifically with application-specific integrated circuit (ASIC) manufacture. In reality, MEMS lacks the high degree of generality characteristic of microelectronics. ICs can be grouped in a limited number of classes, within which design and production follow well-defined and common steps. As a consequence, the price/performance (p/p) ratio allows industry to make profits on complex ICs, and it makes ICs suited for mass production. Silicon-MEMS sensors and actuators, on the other hand, are very specific.*
- Sensor applications also call for complicated, novel packaging schemes and MEMS packaging experience is relatively new. MEMS often have to be in direct contact with their surroundings, and each environment imposes its own constraints. This makes packaging for MEMS relatively more important, in terms of cost and (often) size, than ICs, further illustrating our claim in the Packaging section in Chapter 4, this volume that MEMS design should start from the packaging constraints and work its way to the miniature sensor inside rather than the other way around. Packaging and testing costs as much as 70% of total value MEMS product.
- Successive "bubble busts" [illustrated above in terms of microfluidics for high-throughput screening (HTS) and large optical switch arrays for telecommunications] have scared investors and product planners.
- The market is very fragmented.
- Multidisciplinary knowledge is required.
- There is a lack of capital formation opportunities.
- There is a lack of well-defined direction from roadmaps, industry standards, and industry associations.
- Perhaps equally important has been the lack of marketing skills in the early MEMS companies (and, as Regis McKenna says, "marketing is everything"). A survey suggests that 65% of MEMS gurus entered the field because the technology itself seemed compelling ("technology push"). So, obviously, there was a lack of technology/application matching. Micromachinists initially were too far removed from a detailed understanding of the applications. They were not alert enough to market demands and pushed micromachining technologies they controlled rather than solving industrial problems with the most suitable micromachining technology. In reality a MEMS solution based on a more mature precision engineering technology is as good a solution as one based on, say, surface micromachining.

Lessons Learned

One important MEMS market lesson from the last decade is that only MEMS applications geared toward mass consumption applications are succeeding commercially. As an important consequence, silicon-based MEMS devices (e.g., TI's DMDs, ADI's surface-micromachined accelerometers, and all types of RF-MEMS) must be compatible with existing IC lines to reduce costs. The consumer market should be a strong driving force for the MEMS industry to develop more integrated devices and is pushing the MEMS industry to 8-inch wafer size manufacturing. The need to adhere closer to IC manufacturing rules has become even more urgent, as few U.S. MEMS foundries have survived. As we saw above, the emergence of mass consumer MEMS applications has made MEMS very hot again, and the companies and MEMS foundries that did survive the MOEMS bubble can expect to thrive if they can scale up to compete with traditional IC fabs fast enough. In the author's own experience, MEMS foundries are hard to make profitable in the United States, as they need to keep on accepting a wide variety of jobs to keep the expensive clean-room operation going. In the process, they do not stay long enough on the learning curve of one new product to become world leaders for that particular product. Consequently, these laboratories are moving more and more to Asia, where large companies seem to have more patience in keeping the doors open till the MEMS foundry turns profitable.

* To be fair, for micromachines, the economics dictating profitable IC manufacture do not always apply; a microinstrument—say, a micro-gas chromatograph—may cost considerably more than a typical IC. Moreover, sensors and actuators, often using quite esoteric non-IC type materials, are produced in relatively low volumes and are so very application specific that, in principle, they may command a much higher price tag.

Olympus, in Japan, for example, runs the largest MEMS foundry in the world.[3] Similarly Bosch, in Germany, opened a MEMS foundry in 2005 (Bosch Sensortec). More traditional IC foundries have better survival chances in the United States, but it is worth pointing out that China will control 5% of the IC market by 2010 and the largest number of new 8-inch fabs are in Taiwan and Korea.[3] Although Korea and Taiwan are leading in terms of added capacity in 2007, Japan still holds most of the worldwide capacity, with about 24% followed by Taiwan, the Americas, and South Korea.

In case new non-IC materials and new processes need to be developed for a mass consumer MEMS product, as was the case for TI's digital mirror device, long time commitments (5–10 years) and huge sums of money are required (even with initial government funding) to bring the product to market. Few companies can afford such a large investment of time and money.

Definitions

Introduction

Micromachining marketing studies do not always clarify whether the quoted revenues apply to the micromachine alone or include the micromachine with some ancillary electronics and whether they comprise a higher-level subsystem or describe the whole system. Moreover, the precision machining technology employed often remains unspecified. A good market study should start from a clear definition of the products covered and should specify the manufacturing method.

MEMS

The terms micromachining, microfabrication, micromanufacturing, and MEMS describe the fabrication of devices with at least one of their dimensions in the micrometer range. The acronym MEMS originated in the United States[4] (Figure 10.7) and originally applied exclusively to silicon-based mechanical applications. But just as the twentieth century eventually became the electronics century, the twenty-first century promises to become the age of biotechnology and information/communication technology. This shift has manifested itself so rapidly in miniaturization science that we now see bio-MEMS problems eagerly tackled by electrical and mechanical engineers. Twenty years ago, the MEMS field was dominated by mechanical applications; today, most new applications are either information/communication-related or chemical and biological in nature. As a consequence, today MEMS refers to all subminiaturized systems, including silicon-based mechanical devices, chemical and biological sensors and actuators, and miniature nonsilicon structures (e.g., devices made from plastics or ceramics). The application of MEMS to medical and biotechnology problems is called *bio-MEMS* (which includes microfluidic structures, drug delivery devices, immunosensors, and DNA arrays).

More specific terms, such as MOEMS (e.g., micromirror arrays, fiber optic connectors), RF-MEMS (e.g. inductors, capacitors, antennas), commercial-off-

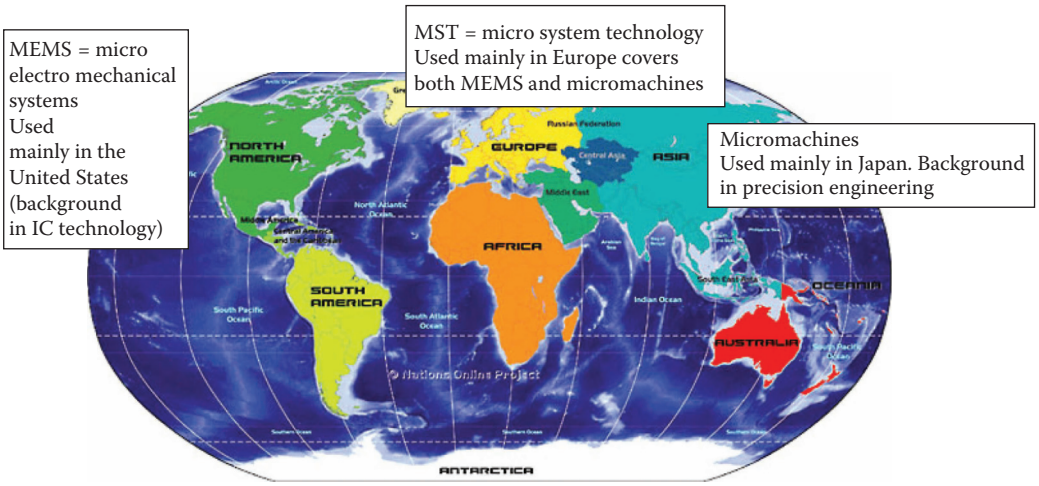

FIGURE 10.7 Micromachining terms around the world.

the-shelf microelectromechanical systems (COTS-MEMS), and high-aspect-ratio MEMS (HARMEMS) have also been introduced, and many more can be expected as many untenured professors want to have at least named something in the MEMS field.

Microsystems Technology

In Europe, the term *microsystems technology* (MST) is more prevalent than MEMS (Figure 10.7). One European definition of MST reads: "A microsystem is an intelligent miniaturized system comprising sensing, processing and/or actuating functions. Normally these would combine two or more of the following: electrical, mechanical, optical, chemical, biological, magnetic or other properties, integrated onto a single multichip hybrid." Alternatively, "A microsystem or microinstrument integrates sensors, actuators, and electronic components on a small footprint, collects and interprets data, makes decisions, and enforces actions upon its environment."[5]

As microsystems are combinations of sensors, actuators, and processing units, they are very application specific. They should be distinguished though from application-specific ICs (ASICs), which can be grouped into a much more limited number of classes within which design and production follow well-defined and common steps.[6]

Micrototal Analysis Systems/Lab-on-a-Chip

Micrototal analysis (μ-TAS) constitutes MST with an analytical function. An alternative term often used is lab-on-a-chip (LOC). In most of the literature today, little distinction is made among MST, μ-TAS, and LOC. Examples of commercial products in this general category are Nanogen's NanoChip™ molecular biology workstation (http://www.nanogen.com) (see Volume II, Example 8.2), TI's Spreeta and handheld reader (http://www.sensata.com/sensors/spreeta-analytical-sensor-highlights.htm) (see Figure 10.47), Caliper's microfluidic LabChip systems (http://www.calipertech.com), RotaPrep's sample preparation stage (Figure 10.51), and Agilent's MicroGC (Figure 10.8). It is important to note that most μ-TAS today still involve sizable instruments. Only some of the components have been miniaturized. Microsystems of this type still carry a price tag similar to that of large instruments ($2,000 to $120,000). The miniaturized components enable some improved

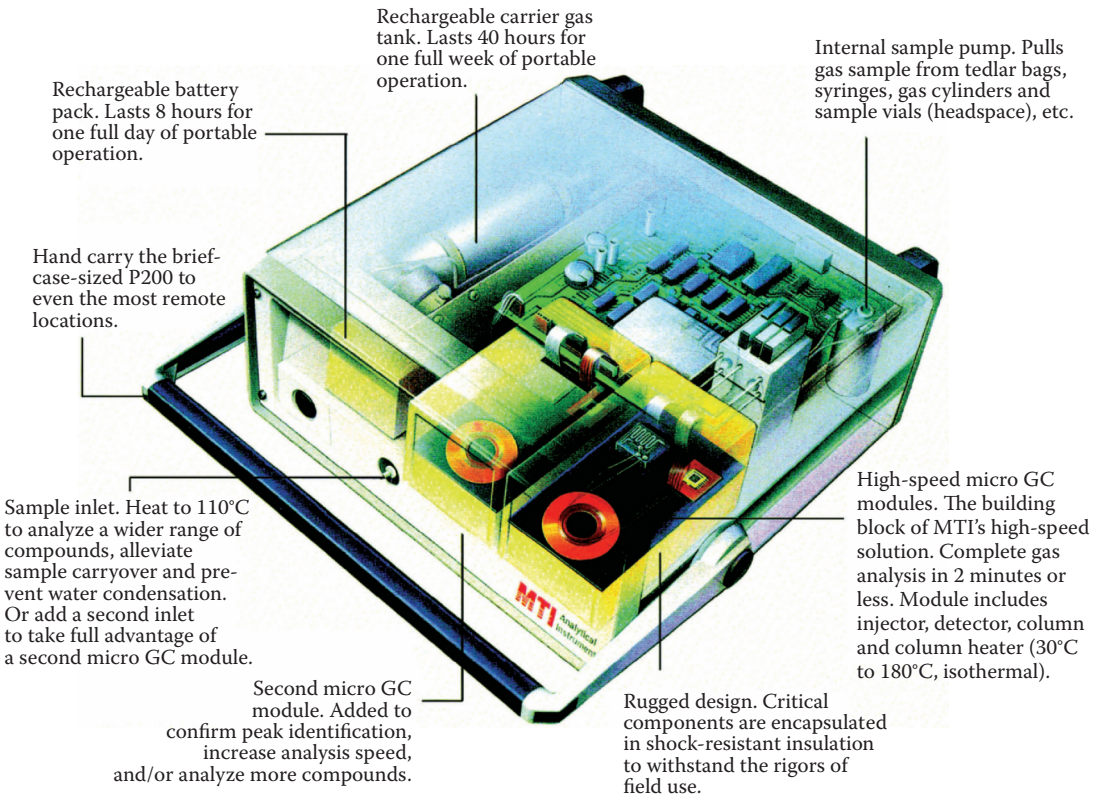

FIGURE 10.8 Agilent's MicroGC (formerly MTI).

functionality, but not yet a lower cost or a smaller, perhaps handheld, instrument. Some of the notable exceptions are the portable surface plasmon resonance sensor (Spreeta) shown in Figure 10.47 (with an instrument of $250 and disposable component of $30) and Johnson & Johnson i-STAT handheld automated blood analyzer, shown in Figure 10.42. The same instrument shown in Figure 10.8, but in a handheld format, would command a price tag somewhere between that of large instruments ($2,000 to $120,000) and sensors ($0.50 to $100), i.e., $200 to $500. To develop more handheld analytical equipment like the Spreeta is one of the μ-TAS challenges that lie ahead. Through the widening of MEMS applications, the word *MEMS* in the United States is more broadly interpreted now, and MST and MEMS have become more or less synonyms.

Micromechatronics

A mechatronics product is defined as a smart device that involves mechanical and electrical principles in design and performs hybrid mechanical and electrical functions. In Japan, the focus has been on micromechatronics or micromachines, defined as follows: "Micromechatronics is the technology that involves the design and manufacture of mechatronics products with dimensions in the range of 1 μm to 1 mm and are capable of performing complex microscopic tasks."[5] (For an example, see Figure 10.9.) In addition to the difference in sizes between mechatronics and micromechanotronics, major differences are in design methodologies, fabrication techniques, and packaging and testing.

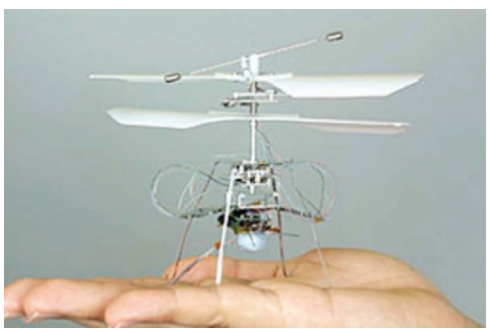

FIGURE 10.9 The world's smallest and lightest micro-flying robot. Epson pioneered the micro-flying robot, based on micromechatronics technology—the world's lightest and most advanced microrobot, which also features Bluetooth wireless control and independent flight.

In micromechatronics, structural components are designed on the base of scaling laws and electromagnetic actuators often are replaced by thermal, piezoelectric, and electrostatic microactuators. Components more often are fabricated by chemical-physical processes than by machine tools. Assembly, packaging, and testing are also different from those in macroscale mechatronics. Whereas MEMS and MST definitions have grown closer together, this Japanese term retains its separate meaning.

Microsensors

A sensor element is a device that converts one form of energy into another (e.g., ZnO, a piezoelectric material, which converts mechanical energy into electricity) and provides the user with a usable energy output in response to a specific measurable input. Measurands may belong to the radiation, thermal, electrical, chemical, mechanical, or magnetic field domains. The sensor element may be built from plastics, semiconductors, metals, ceramics, etc. To qualify as a microsensor, it must have at least one dimension in the micrometer range. Since the early 1980s, the term *sensor element* often invoked the notion of a silicon-built device, but there are many non-silicon-based microsensors.

A sensor includes a sensor element or an array of sensor elements with physical packaging and external electrical or optical connections. Synonyms for "sensor" are *transducer* and *detector*. A sensor system includes the sensor and its assorted signal processing hardware (analog or digital). *Transducer* sometimes refers to a sensor system, especially in the process control industry.

In the case of silicon-based sensors, some additional jargon has developed. A Si sensor element is called a *sensor die*, which refers to a micromachined Si chip. It typically sells for $0.10 to $2 as a commodity product, although the price tag can rise to $50 or more for a high-performance structure sold in smaller quantities. A *silicon sensor* alludes to a first-level, packaged Si die or sensor element with or without basic electronic circuitry. An *integrated silicon sensor* is a monolithic device comprising the sensor and one or more electronic components, which amplify and condition (standardize) the sensor output signal. The standardization of the sensor signal

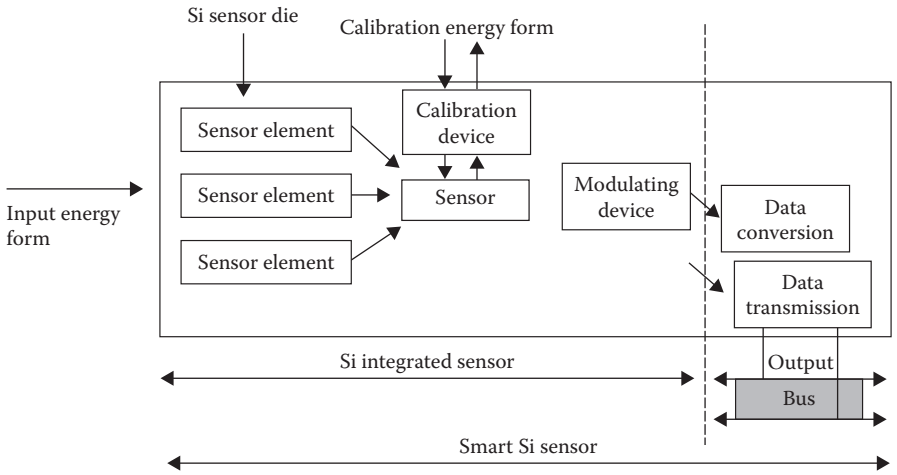

FIGURE 10.10 Definition of a silicon sensor die, a silicon sensor, a silicon integrated sensor, and a smart silicon sensor. (After National Research Council, 1995.)

makes the device bus compatible, enabling efficient communication between the central processor and the sensor. Typical selling prices range from $2.50 for quantities of a million units per year to over $100 for complex sensors in smaller unit quantities. At yet a higher level is a *smart silicon sensor,* which is a packaged integrated sensor containing some part of the signal-processing unit to provide performance enhancement for the user. Signal processing might include autocalibration, interference reduction, compensation for parasitic effects, offset correction, and self-test. The various silicon-based parts defined above are represented schematically in Figure 10.10.

Microactuators

The definition of a sensor element as a device that converts energy from one form into another also applies to an actuator. In the case of an actuator, one is interested in the ensuing action, whereas in the case of a sensor, our interest is in the information garnered. In other words, if the intent is to measure a change, one will refer to a sensor; if the intent is change or action itself, one defines an actuator. The appropriate use of *sensor* or *actuator* is not based on the physics involved but on the intent of the application.[7]

Actuators are components that convert energy into an appropriate action, often dictated by a sensor control unit. They facilitate a function such as opening a valve, positioning a mirror, moving a plug of liquid, etc. Microactuators are actuators with at least some dimension in the micrometer range. Since an actuator "acts," some power is usually needed. Miniaturization of actuators is consequently less obvious than that of sensors, as power does not scale advantageously in the microdomain (power is proportional to the volume, i.e., l^3; see Chapter 8, this volume). To induce micron-scale motion, actuators do not need to be micron-scale themselves. Busch-Vishniac suggests we call the latter *microactuators* in contrast with *microfabricated actuators*, which are micromachined actuators.[8]

The selling price for Si-based actuators in large quantities may range from $5 to $200. A few Si micromachined actuators have reached the commercial market. Examples include Redwood Microsystems' (company now defunct) thermopneumatic valve (Figure 10.11a),[9] TiNi's shape memory alloy microvalve (http://www.sma-mems.com) (Figure 10.11b), and ADI's surface-micromachined accelerometer qualifies (Volume II, Figure 7.92). The latter involves a sensor/actuator combination with a self-test involving electrostatically actuated interdigitated polysilicon fingers (Volume II, Figure 7.93).

Microstructures or Microcomponents

A microstructure or microcomponent refers to a precision machined part that has at least one of its dimensions in the micrometer range but is not a sensor, actuator, or microsystem. Rather, it concerns an item such as a microlens, micromirror, micronozzle, microneedle, etc., that acquires a useful function only when combined with other components. Selling prices of such Si microstructures in large

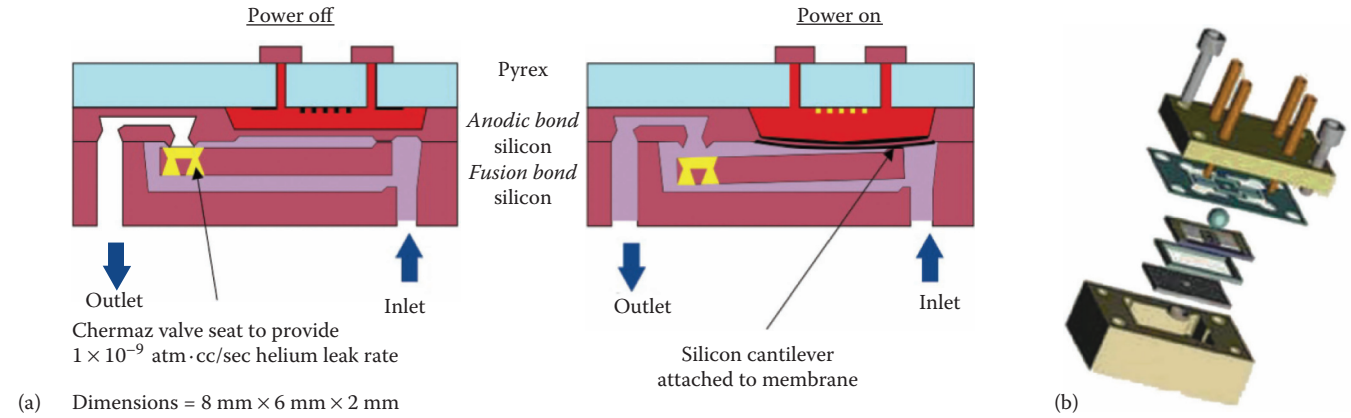

FIGURE 10.11 Examples of commercially available actuators. (a) Thermopneumatic valves by Redwood Microsystems (Fluistor™). Normally closed shut-off microvalve featuring a liquid-filled cavity, which flexes a silicon diaphragm when heated, forcing the valve cover to lift off the valve seat. (After Zdeblick, M. J., R. Anderson, J. Jankowski, B. Kline-Schoder, L. Christel, R. Miles, and W. Weber. 1994. In *Technical Digest: 1994 Solid State Sensor and Actuator Workshop,* 251–55. Hilton Head Island, SC.) (b) TiNi Alloy Company's shape memory alloy valve ($190/valve in small quantities). This is a normally closed microvalve. A current through the NiTi die lifts it from the orifice die. (Courtesy of Dr. D. Johnson, TiNi Alloy Company.)

volumes may range from $0.25 to $100.[10] The latter numbers are hard to confirm, since most microstructures are delivered to clients as part of large development contracts.

An example of a Si microstructure built by the author and his team is the scanning tunneling microscope (STM) cantilever with integrated sharp Si tip shown in Figure 10.12.[11,12] The silicon tip is sharpened by consecutive oxidation sharpening, a process developed by Ravi and Marcus[11] (see also Volume I, Chapter 4, "Orientation and Dopant Dependence of Oxidation Kinetics"). While we delivered the first STM tips to a client company under a best effort-type research and development contract, eventually, these components were sold at a fixed price. Since an STM tip determines the quality of an STM picture, this product is an example of how a small micromachined component might provide a competitive edge to an STM instrument (~$20K to $60K) manufacturer. In this case, it is important that the instrument manufacturer controls the micromachining technology of the crucial microcomponent or, better yet, has it in-house.

First-Level Packaged MEMS and Smallest Commercialized Units

Nexus, a consulting firm on MEMS, makes an important distinction between the first-level packaged MEMS/MST and the smallest commercialized unit.[1] This is illustrated in the case of an ink-jet cartridge

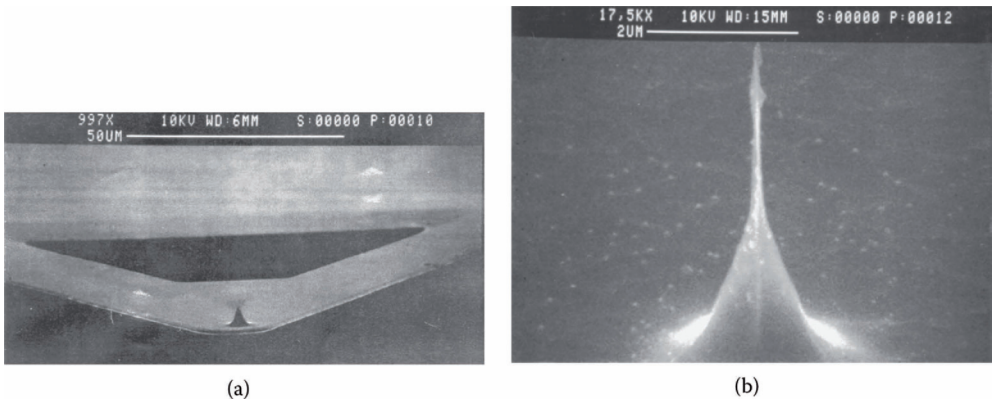

FIGURE 10.12 Example of microcomponent made with silicon micromachining: single-crystal scanning tunneling microscope tip on single-crystal cantilever beam. (a) High-aspect-ratio silicon tip. Photograph taken from a 45° angle. (b) Tip is actually 40% taller than it appears. (From Ravi, T. S., and R. B. Marcus. 1991. Oxidation sharpening of silicon tips. *J Vac Sci Technol B* 9:2733–37; Editorial. 1991. Menlo Park, CA: TSDC [Teknekron]. With permission.)

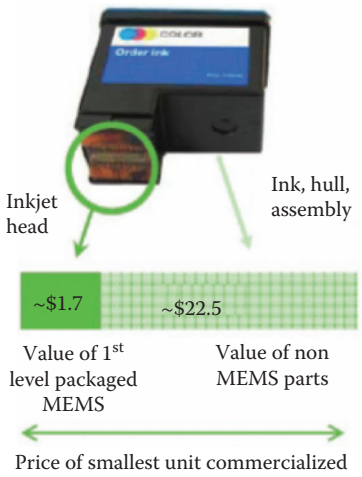

FIGURE 10.13 Example of an ink-jet printer head. First-level packaged MEMS and smallest commercialized unit. (From Nexus. 2006. *Nexus market analysis for MEMS and microsystems III, 2005–2009.*)

in Figure 10.13. One cannot buy ink-jet heads alone, and from the point of view of the market (products sold and bought), the smallest commercialized unit is the cartridge or printer head. The MEMS/MST in the cartridge/printer (~$1.7) is worth much less than the total value of the cartridge/printer (~$22.5).

This simple clarification is very relevant for Si foundries interested in manufacturing the Si die only.

Overall Market for Micromachines

Introduction

Richard Feynman presented two lectures on micromachining: "There's Plenty of Room at the Bottom," at Caltech on December 16, 1959, and "Infinitesimal Machinery," at the Jet Propulsion Labs on February 23, 1983.[13,14] In these now famous lectures, he speculated on the use of micromachining for some esoteric devices such as microfabricated light shutters, probing devices for electronic circuits, and adjustable masks, the first two of which have been realized. He was also convinced of the future of truly three-dimensional circuitry in computers. In general, he doubted the wide applicability of the technology, though. Feynman could not suggest many uses for micromachinery, but he was not worried. He said, "I'm fascinated but I don't know why."

In this section, we investigate applications and overall markets for MEMS and show that the field has matured, with MEMS products now entering consumer electronics so that the market is poised for a major take-off. We conclude with a very positive outlook for MEMS, with the understanding that micromachining be defined as broadly as we have in this book—beyond silicon-based technology and perhaps even beyond batch methods; that is, including continuous manufacturing methods.

Overall MEMS Market Size

The numbers for the overall market size and market projections for miniaturization technology presented here principally are culled from marketing studies and insights by Nexus (http://www.nexus-mems.com), Yole Développement (http://www.yole.fr), Bosch Sensortec (http://www.bosch-sensortec.com), SEMI (http://www.semi.org), Frost & Sullivan (http://www.frost.com), Draper Labs (http://www.draper.com), Wicht Technologie Consulting (WTC) (http://www.wtc-consult.de), Janusz Bryzek (janusz@bryzek.com), and Roger Grace Associates (http://www.rgrace.com).

According to the Nexus Market Analysis for MEMS and Microsystems III 2005–2009,[1] the MEMS/MST market volume was worth $12 billion in 2004 and was expected to reach $25 billion in 2009. The growth was projected to be rapid, with a 16% compound annual growth rate (CAGR) in value in the period 2004–2009 (Figure 10.14). We like to point out that the 1998 Nexus Task Force[5] projected a MEMS/MST market for 2002 of $38 billion already. Obviously, a more detailed analysis about the real MEMS/MST contribution has made for a more careful forecast in this latest report. Considering the traditional Nexus definition used in earlier reports—the market for the smallest unit, incorporating MST component(s), that is commercially available—the market was expected to increase from $36 billion in 2004 to $52 billion in 2009 (Figure 10.14).

In 2005, according to Yole (http://www.yole.fr/), more than half of Si-based MEMS by value, which this consulting firm estimates at $2.6 billion, were produced in North America. Japan was the next largest MEMS producing region, accounting for one-fifth of the total 2005 MEMS revenues ($1.1 billion). About 16% of MEMS sales, over $815 million, originated from European production. Singapore was also a significant manufacturing location for MEMS

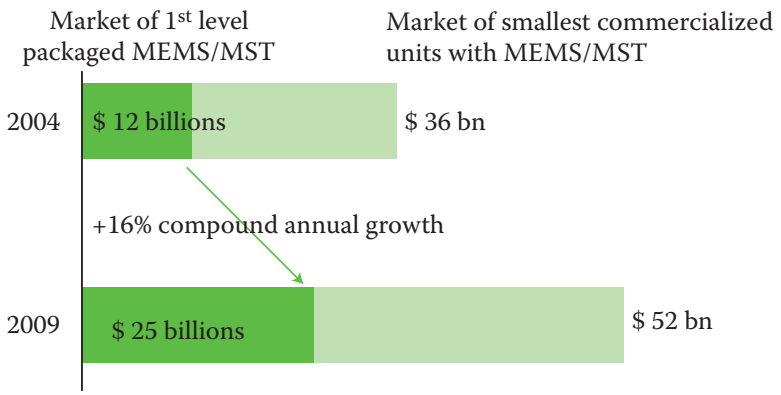

FIGURE 10.14 Total market for microelectromechanical system/microsystems technology in 2004 and projections for 2009. (From Nexus. 2006. *Nexus market analysis for MEMS and microsystems III, 2005–2009.*)

manufacturers (e.g., STMicroelectronics with ink-jet heads), with 11% of MEMS device revenues attributed to Singapore fabs. The MEMS industry is highly fragmented with a large number of device manufacturers worldwide in a wide variety of application fields. Many start-ups and small and medium-sized companies participate in the industry. In 2004, there were 230 manufacturers of MEMS products. Most of these were developing new products, some of which are just starting to significantly affect the market. The top thirty MEMS device manufacturers accounted for about 84% of MEMS device sales in 2005. No single device manufacturer has reached the billion-dollar sales mark as of yet: the average revenue for a top thirty manufacturer is about $147 million (http://www.yole.fr/pagesAn/products/semi.asp).

In Table 10.2 we list 2005 MEMS sales of some important MEMS companies. The top three MEMS companies today are TI, Hewlett-Packard, and Bosch.

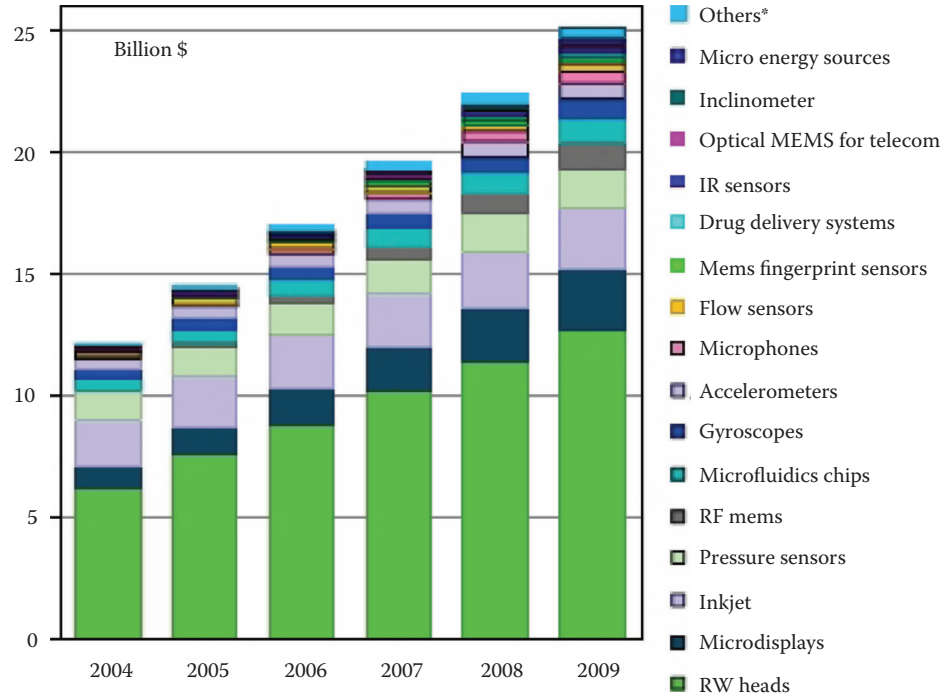
In Figure 10.15 we show the Nexus market breakout for sixteen types of first-level packaged MEMS/MST (a seventeenth category, "other," includes microreactors, chip cooler, inclinometers, memories, fingerprints, liquid lenses, microspectrometer, wafer probes, micromirrors for optical processing,* micropumps, micromotors, and chemical analysis systems).[1] According to this breakout, the MEMS/MST market in 2009 was still 70% made up of only three products: read-write (RW) heads, ink-jet heads, and microdisplays. RW heads still represented around 51% of the market in 2009: while traditional application of RW heads in PCs would grow only moderately, the RW market was experiencing a renaissance in consumer electronics, as hard discs were entering music players (e.g., in many iPod models) and smart phones [Samsung introduced the first cell phone with a hard disc drive (HDD) in 2004], as well as digital video cameras, set-top players, and DVD recorders. It is important to note that MEMS will lose a very important market when HDDs are replaced by solid state disc (SSD) memory (a flash drive), as both RW heads and accelerometers will fall away. There are a lot of arguments to suggest that SSDs will replace HDDs in many applications. The SSD market is growing fast, approximately doubling in revenue every year for the foreseeable future. In the long term (5–10 years) the trusted HDD will eventually retire, to be replaced by the flash drive.

Ink-jet heads continued to be one of the most profitable markets for MEMS. MEMS microdisplays are the new MEMS blockbuster, and their revenues were expected to overtake ink-jet heads in 2009. TI was forging ahead with the digital light processing (DLP) chip for projectors and for front projection

TABLE 10.2 Sales (in 2005) of Microelectromechanical System Products by Some of the Largest Players

Company	Sales ($, in Millions)
Texas Instruments	788
Hewlett-Packard	750
Bosch	325
Lexmark	230
ST Microelectronics	200
Seiko	199
Cannon	184
Freescale	182

* In Figure 10.15, Nexus somehow has digital micromirrors categorized under both *other* and *microdisplays*.



* Others: Microreaction, chip cooler, inclinometers, MEMS memories, MEMS fingerprints, liquid lenses, microspectrometer, wafer probes, micro-mirrors for optical processing, micro-pumps, micromotors, chemical analysis systems

FIGURE 10.15 Nexus market breakout for first-level packaged microelectromechanical system/microsystems technology devices.[1]

and rear projection TVs (home theater). Three other products that, according to Nexus, would make each over $1 billion in sales in 2009 are pressure sensors, RF MEMS, and inertial sensors.[1] Other fast-growing markets were microphones and tire pressure monitors, next to established pressure and motion sensors, which were increasingly being driven by consumer electronics.

The relative contributions to various application fields of these MEMS/MST for the years 2004 and 2009 are illustrated with two pie charts in Figure 10.16. The three dominant application fields were IT

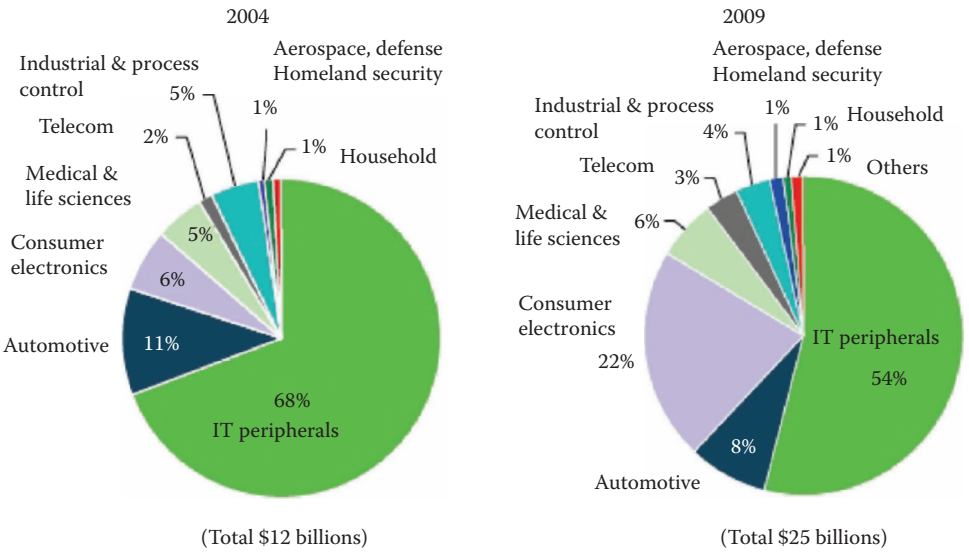


FIGURE 10.16 The relative contributions to various application fields for microelectromechanical system/microsystems technology products for 2004 and projections for 2009. (From Nexus. 2006. *Nexus market analysis for MEMS and microsystems III, 2005–2009.*)

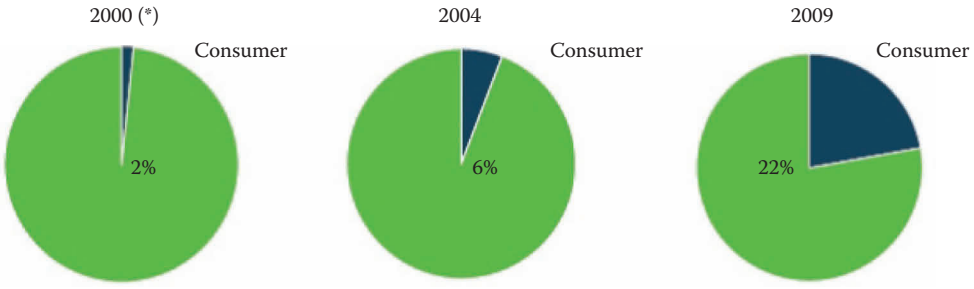

FIGURE 10.17 MEMS in consumer products will have gone from less than 2% of the MEMS/microsystems technology market in 2000 to 22% in 2009. (From Nexus. 2006. *Nexus market analysis for MEMS and microsystems III, 2005–2009*.)

peripherals, automotive, and consumer electronics. IT peripherals were expected to remain by far the first application field of MEMS and MST in 2009, mainly with RW heads and ink-jet heads. However, the share of IT peripherals was expected to decrease from 69% to 54%. The biggest predicted change was in the area of MEMS in consumer electronics (CE) that was predicted to grow from less than 2% of the MEMS/MST market in 2000 to 22% in 2009 (Figure 10.17). Consumer electronics were expected to drive the MEMS market growth for the remainder of this decade. The three drivers for MEMS in consumer electronics were 1) large-screen high-definition television for everybody (rear projection and front projection home theater TVs), 2) more storage in digital equipment (with HDDs that enter digital video cameras, music players, smart phones, set-top players, and DVD recorders), and 3) mobile handsets (with accelerometers today, and tomorrow gyros, microdisplays, micro fuel cells, fingerprint sensors, zoom sensors, gas sensors, weather stations, projection displays, etc.).

Automotive applications were expected to remain a major MEMS field, with several killer application fields, such as airbags and tire pressure monitoring system (TPMS). The numbers of MEMS for this application would still grow at a rapid pace; however, the growth in revenue was expected to be moderate due to a continuous pressure on prices (e.g., gyroscopes increasing 15% per year in units but only 8% in revenue).

Yole analyzes the overall MEMS market structure a bit differently. It introduces a MEMS supply chain, as shown in Figure 10.18, and distinguishes among MEMS-based systems, MEMS alone, front-end equipment, and materials and chemicals.[15] Also, the Yole MEMS numbers refer to Si technology only, so they do not include, for example, RW heads, which are not silicon-based.

According to Yole, the worldwide MEMS systems market reached $40 billion in 2006 and was expected

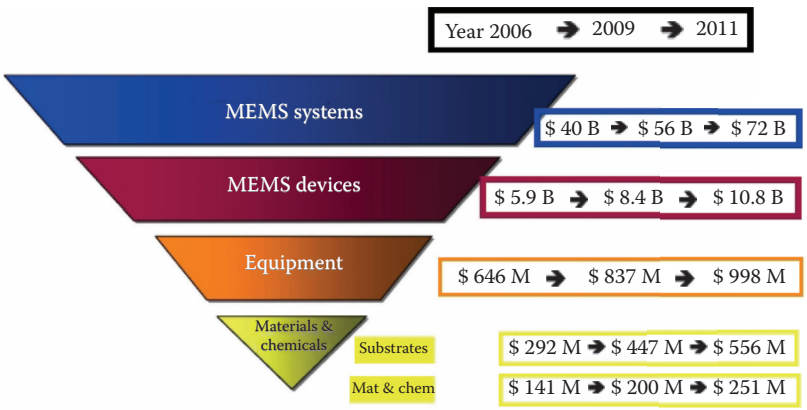

FIGURE 10.18 Yole's microelectromechanical system (MEMS supply chain from 2006 to 2009 to 2011. (From Yole. 2007. Evolution of the MEMS markets and evolution of the MEMS foundry business. *Transducers*.)

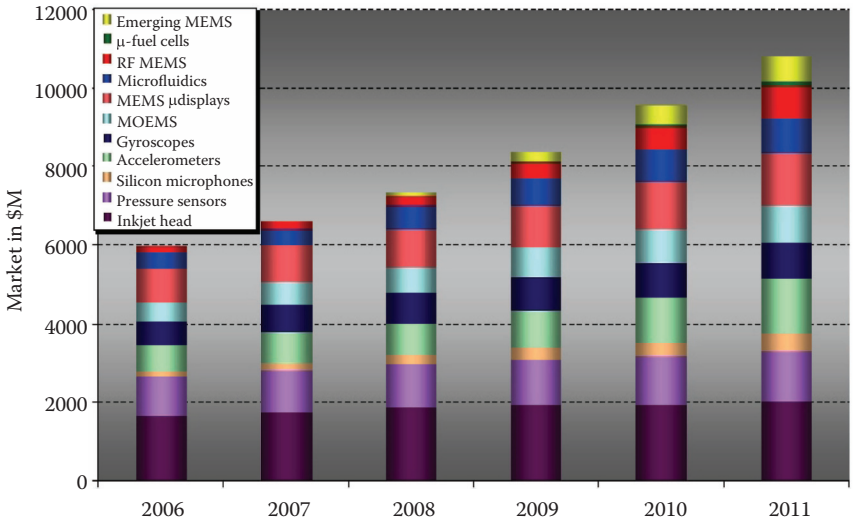

FIGURE 10.19 Global microelectromechanical system market for 2006–2011, according to Yole.

to rise to $56 billion by 2009 and $72 billion by 2011, for a compound annual growth rate (CAGR) of about 15% over the five-year period.[15] Globally, the MEMS market was $5.9 billion in 2006 and was forecast to grow to $8.4 billion in 2009 and to $10.8 billion in 2011, with a 13% CAGR. The MEMS equipment market was $646 million worldwide in 2006 and was expected to expand to $837 million in 2009 and to $998 million in 2011. The five-year CAGR forecast for MEMS equipment was 6%. MEMS materials can be divided into substrates and chemicals and other materials. Together these markets totaled $433 million in 2006 and were forecast to be $807 million in 2011. MEMS materials are expected to grow at a five-year CAGR of 15% through 2011.[15]

The global MEMS market for ten different products and one category called *emerging MEMS*, over the period 2006–2011, according to Yole, is illustrated in Figure 10.19.[15] These numbers are only 1/3 of the Nexus numbers, mostly because Yole does not include RW heads (which are not based on Si technology; Yole's market study is Si-centric) and because under its Emerging MEMS category, Yole is considering some other MEMS products than Nexus lists in its Others category.

Yole puts the ink-jet head market at $1.8 billion in 2006 and expects it to grow to $2 billion in 2011. Although digital imaging is a strong driver for this relatively mature market, Yole expects that the overall trend toward nondisposable ink-jet heads will dampen volume growth for this application.

As in the Nexus report, Yole sees a big change in the MEMS market today in that an important part is now driven by the growth of consumer electronics, which is new in MEMS industry. The period from 2007 to 2011, Yole claims, will certainly see the dominant growth of consumer applications compared with automotive, industrial, and/or medical business. This move toward the consumer applications also is pushing the MEMS industry to 8-inch wafer size manufacturing, and this means more involvement of IC foundries in MEMS business. This switch to 8-inch wafer has a lot to do with the increase of ink-jet head die size and the transition to 8-inch by TI for digital mirror production.

Fast-Changing MEMS Market Characteristics

The very large projected markets for MEMS in market studies published before 2000 are realistic only if nonsilicon approaches are included (e.g., thin-film RW heads) or a first-level system in which the MEMS technology is embedded is counted as well. After the 2001 optical and fluidic MEMS bubbles, major changes in the markets for mechanical and MOEMS devices (RW heads, ink-jet heads, pressure sensors, accelerometers, gyros, digital micromirror arrays, microphones, etc.), are causing upward revisions of MEMS market projections again. These types of MEMS are now experiencing a growth spurt because of their incorporation in consumer products (cars, mobile phones, games, PCs, cameras, etc.). Mechanical and MOEMS largely are made

with IC-based techniques, and the cost of ICs can be lowered only when the quantity of parts numbers in the millions per year. Consequently for silicon-based sensors to succeed on the same scale as ICs, the current manufacturing environment dictates that one must concentrate on mass consumption products such as cars, PCs, air conditioners, TVs, cell phones, vacuum cleaners, toys, printers, and dishwashers. This transition to consumer products has finally happened for optical and mechanical MEMS, and for these products the market dynamics have now become similar to those of the IC market. Consequently MEMS growth is expected to follow a hockey stick growth curve, with the total value of MEMS rising, according to one market report, to $40 billion in 2015 and $200 billion in 2025 (Dr. Marinis from Draper Laboratory: http://www.sem.org/PDF/s01p01.pdf). The problem now is more one of profitability rather than the absence of real product opportunities, i.e., sensors will become smaller and smaller, more and more integrated and manufactured on larger (8-inch) Si wafers. In a sense, one might say that the IC industry has swallowed the mechanical and MOEMS field. The more established MEMS such as accelerometers (ADI), ink-jet heads (TI), and RW heads (IBM, Hitachi) are exploited now mostly by large companies. The involvement of MEMS and IC foundries is on the rise as well, and the tremendous cost pressure is driving more and more MEMS manufacturing overseas.

However, one must still make a distinction between ICs and MEMS. There are about 50,000 types of sensors to measure 100 different physical and chemical parameters,[16] so often only 1,000 to 10,000 are needed a year. We can conclude that fragmentation remains the outstanding characteristic in the sensor market. This often excludes integrated semiconductor solutions, even though they might be technically superior. Cost/performance improvement does not always justify the application of IC technology, and hybrid approaches remain an important option especially in microinstrumentation and for chemical sensors. The dynamics of the market for MEMS-based microinstrumentation is, furthermore, different from that of ICs in that MEMS instrumentation can command considerably higher price tags (say, hundreds of dollars rather than $10 or less). In the latter case, smaller numbers of parts may be offset by a higher profit margin. The situation has been compared to that of application-specific integrated circuit (ASIC) manufacture, leading to the acronym ASIS (application-specific integrated system). Hybrid technology will be employed in this case not solely out of cost considerations but because one monolithic manufacturing technique is unlikely to deliver the bandwidth in feature sizes and material types necessary to cover the various needs common in small instrumentation.

The situation for disposable biosensors (e.g., glucose sensors) applied to diagnostics is very different again. In this nascent field one competes with industrial giants and with very efficient established manufacturing processes. In the bio-MEMS field, to succeed similarly to the mechanical and MOEMS

Table 10.3 New MEMS Companies and Products

Company	Product	Where
Silmach	Silicon-based micromotors for the watch industry	France
Perpetuum	Energy harvesting systems using MEMS as building blocks	United Kingdom
Rhevision Varioptic Siimpel (United States)	Liquid lenses for consumer applications	United States France United States
Lilliputian Systems	MEMS-based micro-fuel cells	United States
Qualcomm Liquavista	Innovative microdisplays	United States Netherlands
SiTime Discera Silicon Clocks VTI Technologies	MEMS-based oscillator	United States United States United States Finland
Microvision Philips	New optical microelectromechanical system applications	United States Netherlands

area, one will need to develop mass manufacturing techniques based on very large batches or roll-to-roll manufacturing on paper on plastic substrates.

Most of the risk taking in innovative MEMS concepts is still by U.S. entrepreneurs, although activity in Europe and Asia has picked up, as is clear from the list of new MEMS companies in Table 10.3. There remains about a three- to five-year delay in time between start-up activity in the United States and Europe on a specific subject (e.g., U.S.-based Affymetrix, created in 1992, versus the European OMM in 1996). So far, even successful MEMS start-up companies remain two orders of magnitude smaller than companies in the mainstream IC market.

MEMS Market Segments

Introduction

We consider four MEMS market categories: MEMS in the automotive market; MEMS in medical and biotechnology markets (bio-MEMS); MEMS in industrial automation, including environmental monitoring markets; and MEMS in IT peripherals and telecommunications markets.

MEMS in the Automotive Market

Introduction

Nexus did forecast the number of passenger vehicles, sport-utility vehicles, and light trucks produced globally to reach an estimated 68 million per year by 2009 (add another 15 million for other vehicles, such as buses, trucks, the Popemobile (smile, please), etc.).[1] In a complex electronic/electromechanical system such as the modern car, the need for effective, accurate, reliable, and low-cost electronics and sensors is pressing. While in 1980 electronics accounted for merely 2% of the total cost of a car, today it has reached almost 20%, and it was estimated that by 2010, electronics and software would account for up to 40% of the value of a car (see Figure 10.20). MEMS are making for a larger and larger contribution to this electronic content.

New vehicles feature increasingly sophisticated engine management and safety systems, while a larger number of sensor systems are making their way into lower-priced cars, fueling the overall growth

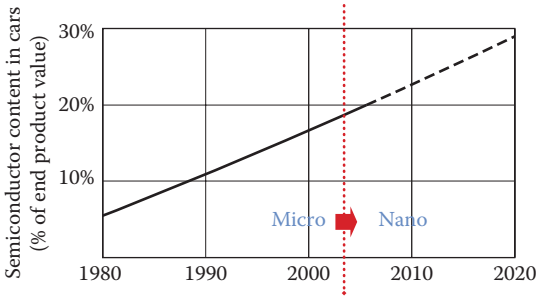

FIGURE 10.20 Semiconductors underpin all business sectors. It was estimated that by 2010, electronics and software would account for up to 40% of the value of a car.

of MEMS in the automotive sensor market. Today, typical mid-sized vehicles contain more than 50 sensors and luxury-class cars more than 100. About one-third of these sensors are MEMS-based, including frontal impact airbags, tire pressure monitoring systems (TPMS), and engine monitors to improve fuel efficiency and lower toxic emissions. This trend will continue as governmental regulations and the needs of the consumer drive auto manufacturers to provide improved safety, quality, and comfort in vehicles. The total market for silicon-based MEMS in safety systems, vehicle navigation, engine management, and cabin comfort, according to a Nexus market report, was $1.29 billion in 2004, and was expected to grow at 9% CAGR to reach nearly $2 billion in 2009, as illustrated in Figure 10.21.[1] Between 2000 and 2004, the largest growth in MEMS applications occurred in the automotive market, with applications expanding to the point that a typical automobile contains twenty-five silicon MEMS devices. Pressure, acceleration, and gyros dominate the present Si MEMS automotive market. The technologies involved are mostly Si bulk micromachining and polysilicon surface micromachining.

Even though the quantity of MEMS devices sold into the automotive market is expected to continue climbing steadily, the automotive percentage of the total MEMS market is actually expected to decline, as the consumer electronics category expands.

When considering all automotive sensors (not only MEMS), the worldwide market was more than $10 billion in 2005, and it was expected to continue to increase at an average annual growth rate of 6% to $14.2 billion in 2010. From automotive sensors, speed and position (38%) and oxygen (20%) sensors would

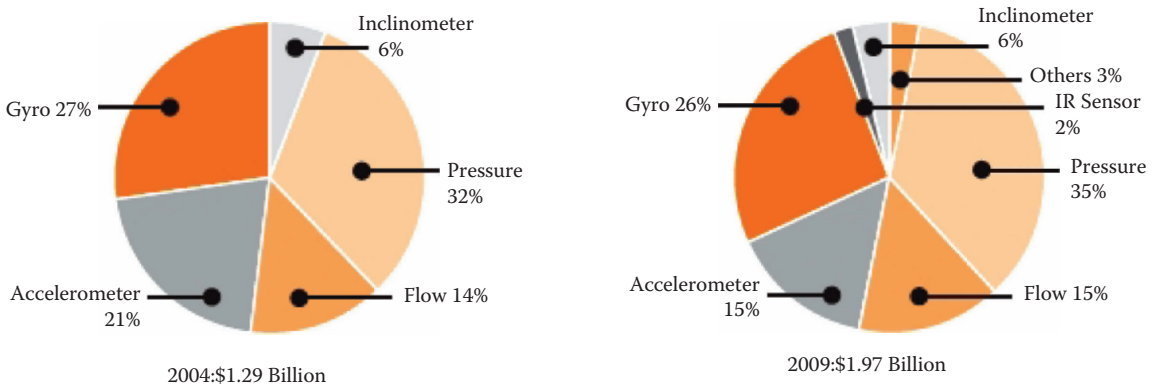

FIGURE 10.21 Various silicon microelectromechanical system sensors in passenger vehicles. (From Nexus. 2006. *Nexus market analysis for MEMS and microsystems III, 2005–2009*.)

remain the largest market segment, rising from $6.2 billion in 2005 to $8.6 billion in 2010 (58%) [*Automotive Sensors*, November 2005 (http://www.the-infoshop.com/study/bc34281-automotive-sensors.html), and Automotive Sensors Market Emerging & Current Sensors Update Now and Future, September 2005 (http://www.researchandmarkets.com/reportinfo.asp?report_id=307920)].

A most important automotive chemical sensor is the so-called *lambda probe*, a solid state oxygen sensor (all new European cars are fitted with a minimum of two lambda sensors). The lambda probe involves traditional ceramics manufacturing, but planar, micromachined oxygen sensors are gaining ground (see Volume II, Figure 9.24).

Many other opportunities for micromachining in automotive sensing exist; a list of sensor needs (met and unmet) in the automotive and transportation industry in general is presented in Table 10.4. There is a continuing migration in the automotive industry from larger electromechanical automotive components to MEMS. In Table 10.5 we summarize this trend. The newest automotive applications for MEMS include better exhaust monitoring devices, wireless sensors for engine management systems, and energy scavengers that harness the energy generated from rotational or vibratory movements within the vehicle as a future power source for TPMS.

Figure 10.22 shows where some of these sensors are positioned in a car. Component cost is a significant factor in the selection criteria of automotive systems designers. Getting your MEMS sensor into a car might take anywhere from seven to ten years. The cost of a MEMS device itself constitutes one-third or less of the total delivered component cost (often $10 or less!). Over 50% of the cost of a typical sensor is in calibration and testing, highlighting the need for innovation. Therefore, a significant challenge to achieve highly efficient design for manufacturability and testing is imposed on all suppliers who wish to be successful in the automotive sector. As a consequence, the use of IC-compatible process lines for MEMS production is growing. There clearly are important benefits in using CMOS or BiCMOS-compatible manufacturing lines to target high-volume MEMS markets, such as the automotive market, and toward adoption of more integrated solutions.

Pressure

Introduction and Market Perspectives

Pressure measurements are absolute, relative, or differential. For most pressure sensors, the common design element is made from a thin, flexible diaphragm that deforms elastically in response to an applied force. Diaphragm thicknesses in these sensors typically range from 20 μm to several millimeters and employ steel, ceramic, or silicon. The ceramic capacitive pressure sensor has a diaphragm cut from relatively thick "cast" sheets of ceramic (e.g., from Kavlico). According to an analysis by Frost & Sullivan (http://www.sensors.frost.com), pressure sensors represent one of the most broad, mature, but very fragmented sensor markets (similar to temperature sensors). In the study "Pressure Sensors and Transmitters Market," the company reveals that the market for all pressure sensors earned revenue of $4 billion in 2004 and projects that this market

Table 10.4 Examples of Sensors and Other Micromachined Components in Use or Needed in Transportation Context

Micromachine	Application	Status
Accelerometers	Airbag release, vehicle dynamics control, antilock braking systems, antitheft systems, active suspension control, headlight leveling	Micromachined products are on the market replacing the old "ball and tube" approach
Air flow sensor	Air/fuel ratio control	On the market but expensive
Alcohol sensor	Detection of alcohol level in blood	No reliable products available
Angle and position sensor	Throttle valve angle, pedal angle or position, and steering angle	All are available
Angular rate sensor	Vehicle dynamics control, navigation, and rollover systems	Available
Azide sensor	Airbag propellant	Does not exist
Battery sensor charge/ density	Charge/density of electrolyte	Research
Contraband detector	Customs	No good solutions
Driver identification	Theft prevention	Some solutions available
Head-up display	Information on window	Not affordable yet
Humidity sensor	Cabin climate	Unsatisfying products available
Level sensor	Oil and gas level	Available
Light sensor	Turn on the lights	Available
Micronozzle system	Fuel injection	Available
NOX sensor	Pollution control	Not available
Oil quality monitor	Engine protection	Not available
Oxygen sensor (two are required in all new cars in Europe)	Air/gas ratio	Available, but new technology is needed for more demanding applications
Pressure sensors	Air intake control (manifold absolute pressure), turbocharger pressure, oil pressure, atmospheric pressure, fuel-tank pressure, brake pressure, climate control, fuel pressure, tire pressure (by September 2007, 100% of the vehicles sold on the United States markets were required to have a tire pressure monitoring system)	Micromachined sensors exist and are on the market and replacing LVDT technology
Parking sensors	Collision avoidance	Acoustic technology available
Rain sensors	Automatic	Technology available
Road/bridge condition sensors	Preventive road maintenance	Not available
Road sensors	Roughness, ice, rain	Not available at cost
Rotational speed and phase sensors	Wheel speed for antilock braking system, engine speed, camshaft, and crankshaft phase for motor control, gear shaft speed for transmission control	Available
Smart windows	Defog, clear view	Not available at low cost
Solid state cameras	Looking behind truck or car	Available
Spill detector	Clearing of truck accidents	No good solutions available
Temperature sensors	Inside and outside vehicle	Available
Torque sensors	Work	Under development

will reach $5.6 billion in 2011. The major industry sectors for pressure sensors are automotive, medical, industrial and process control, aerospace, and military. Household items and consumer products represent upcoming market opportunities.

According to Nexus, narrowing the survey down to silicon-MEMS pressure sensors, sales for first level packaged devices in 2004 were $1.084 billion, and they were expected to grow at a 7% CAGR, resulting in a $1.696 billion market in 2009.[1] Narrowing the scope of the survey even further, the automotive Si pressure sensor market was $408 million in 2004, and revenues for 2009 were expected to amount to $677 million (a 10% growth rate). Silicon

Table 10.5 Migration Status of Automotive Sensors from Large Electromechanical to MEMS

Application	Previous Approach	MEMS Approach	Status
Coolant pressure	Ceramic capacitive	Bonded silicon strain gage	Available (e.g., Keller, SSI Technologies, Fasco)
Exhaust gas recirculation pressure	Ceramic capacitive	Bulk-micromachined silicon	Available (e.g., Ford, Chrysler)
MAP	LVDT	Bulk-micromachined silicon	Mature (e.g., Delco, Nippondenso, Bosch) and more and more replaced by MAF
Airbag accelerometer	Breed "ball and tube" TRW Teknar "rollamite"	Surface and bulk-micromachined silicon	Mature (Analog Devices, Motorola, SensoNor, Delco, and Nippondenso)
Rate sensor	Piezoelectric	Surface and bulk-micromachined silicon	Available (Daimler Benz, Delco, Bosch)
MAF sensor	Hot wire anemometer	Surface-micromachined silicon	Available (Bosch)
Tire pressure	Not applicable	Bulk-micromachined silicon	Available (Sensonor, Motorola, TRW NovaSensor)
Oxygen sensor	Ceramic casting of YSZ	Green tape laminated planar zirconia sensors	Available but expensive (e.g., NGK's UEGO sensor)

Source: Expanded and updated from http://www.rgrace.com/Papers/auto2.htm.

MEMS costs for pressure sensors have come down from $1000 in the 1960s to $10 in the mid-1980s and, in some cases, less than $0.50 today (varies with application-mostly determined by the required packaging and testing). Pressure sensor applications in the automotive industry are listed in Table 10.4 as manifold absolute pressure (MAP), turbocharger pressure, oil pressure, barometric air pressure (BAP) sensor, fuel-tank vapor pressure, brake pressure, climate control, and tire pressure. According to the pie

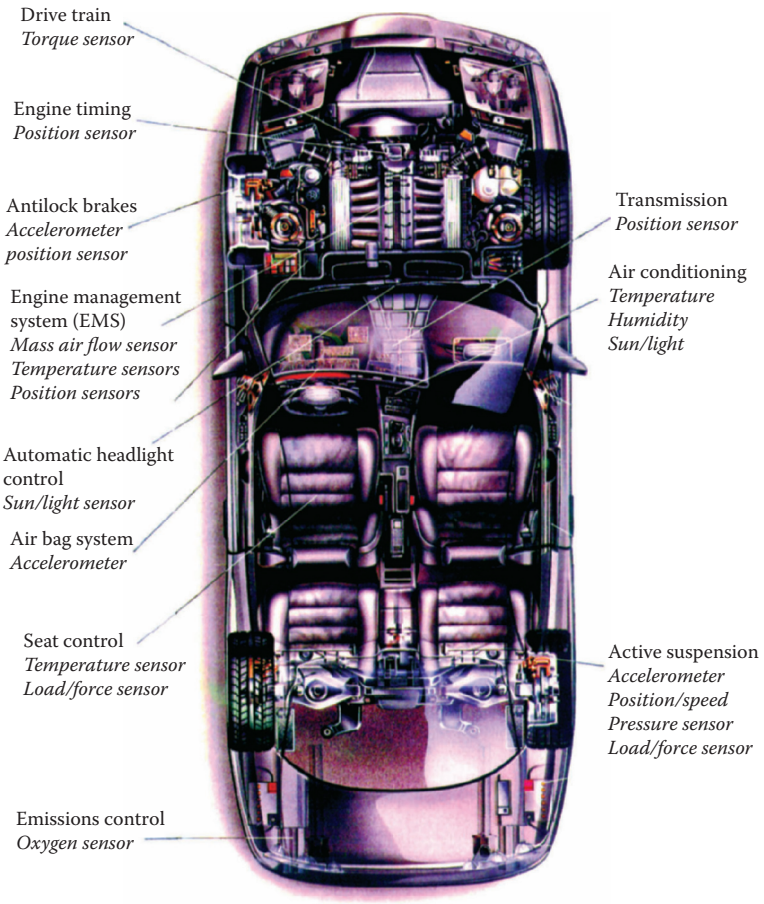

FIGURE 10.22 Automotive sensors.

Table 10.6 Comparison of Pressure Sensor Technology

Parameter	Piezoelectric	Piezoresistive	Capacitive
Self-generating	Yes	No	No
Impedance	High	Low	High
Signal level	High	Low	Moderate
High temperature	Yes	No	No
Accuracy (full scale)	±1%	±1%	±0.2%
Static calibration	No	Yes	Yes
Rugged, high sensitivity	Yes	No	Yes
Damped designs	No	Yes	Yes
Cost	High	Low	High
Electronics required	Yes	No	Yes

(For resonant techniques, see Table 10.7.)

chart in Figure 10.21, pressure sensors will make for 35% of the automotive silicon sensors in 2009 (http://www.wtc-consult.com/cms/cms/upload/PDF/Nexus_Sample_PressureSensors.pdf).

Two main varieties of Si pressure sensors used in cars are piezoresistive and capacitive. In a capacitive design, a thin diaphragm forms one plate of a two-plate device that detects capacitance changes when the diaphragm deflects. In a piezoresistive approach, deflection is measured by the change in the resistance of the silicon strain elements on the diaphragm, or directly in the diaphragm with resistors implanted into the silicon diaphragm. These pressure sensor approaches are compared with a more traditional piezoelectric sensor approach in Table 10.6. A fourth approach is based on resonant structures, as discussed below (see "Resonant Beam Sensors") and compared with piezoresistive and capacitive in Table 10.7. Also, two major manufacturing options are employed for capacitive and piezoresistive pressure sensors: bulk micromachining in single-crystal Si (SCS) and surface micromachining in polysilicon. Recently, Bosch has developed a third pressure sensor manufacturing technology: advanced porous silicon membrane (APSM). This technology makes use of porous silicon to form a cavity underneath the surface of the monocrystalline silicon, which helps to make the wafer manufacturing process fully CMOS compatible and turns the traditional bulk-micromachining process into a surface technology (see Volume II, Figure 4.78). Silicon pressure sensors cover a range spanning vacuum, low pressure (0.02 to 0.1 bar), medium pressure (0.25 to 10 bar), and high pressure (60 to more than 1000 bar).

A capacitive pressure sensor is more sensitive, is less temperature dependent, and holds up better in harsh environments than a piezoresistive one. If one relies on bulk micromachining for the manufacture of a capacitive pressure sensor, it must be carved out of a larger piece of Si to attain the same sensitivity as a piezoresistive sensor, making it more expensive. The electronics for a capacitive pressure sensor are more complicated and expensive. Most of all, in the case of a capacitive sensor, the small signals necessitate integration of sensor and electronics on the same chip. Thus, piezoresistive devices provide higher output signals and are smaller than capacitive sensors, but they require temperature compensation that may be integrated within the same silicon substrate.

The major suppliers of pressure sensors include Honeywell (United States), Bosch (Germany), Infineon (Germany), Freescale (United States), Denso (Japan), Delphi-Delco (United States), All Sensors (United States), Melexis (United States), Integrated

Table 10.7 Performance Features of Resonant, Piezoresistive, and Capacitive Sensing

Feature	Resonant	Piezoresistive	Capacitive
Output form	Frequency	Voltage	Voltage
Resolution	1 part in 10^8	1 part in 10^5	1 part in 10^4–10^5
Accuracy	100–1,000 ppm	500–10,000 ppm	100–100,000 ppm
Power consumption	0.1–10 mW	≈10 mW	<0.1 mW
Temperature cross-sensitivity	-30×10^{-6}/°C	$-1{,}600 \times 10^{-6}$/°C	4×10^{-6}/°C

Automotive Pressure Sensor Examples

Introduction

Historically, pressure sensors in the automotive industry were used predominantly in engine management, e.g., for the measurement of manifold air pressure (MAP) at up to 5 bar. Silicon MEMS pressure sensors have been used in the automotive industry for many years; Bosch, for example, introduced its first Si pressure sensor for the automotive market in 1993. A MAP sensor determines air intake pressure to provide feedback on the correct air-fuel mixture for pollution control and fuel efficiency. Barometric atmospheric pressure (BAP) sensors compensate the air-fuel mix according to altitude. Fuel vapor pressure monitoring is a mandatory requirement on new U.S. vehicles (since 2006). Oil pressure sensors can be either ceramic capacitive, silicon strain gauges (bonded and fused to membranes), or piezoresistive, with silicon chips in silicone oil-filled reservoirs and capped by stainless steel diaphragms. Also, pressure sensors are used in high-pressure fuel injection systems, coolants, braking, and so forth.

A new market opportunity for Si pressure sensors is the direct tire pressure monitoring system (TPMS), a mandatory requirement on new U.S. vehicles (see below). Side airbags and passenger occupation detection are two additional required applications. The pressure sensor competes against accelerometers in the first case and with an infrared low-resolution imaging array in the latter. Other solutions for passenger detection include iBOLT from Bosch, which uses Hall-effect sensors. Pressure sensors react faster in the event of a side impact and are available on the BMW 5 series cars.

Automotive pressure sensor sales are projected to grow at 10% as a result of increased deployment in engine management applications such as BAP and TPMS. Side airbags and occupancy detection systems, where several different solutions are expected, will also help spur sales of automotive sensors. TPMS is driven by legislation and was expected to exceed $200 million in 2009.

Manifold Absolute Pressure Sensor

A prime example of a Si pressure sensor in the automotive application is the MAP sensor, used to control the air-fuel ratio in the engine's management system. Prices, in 2004, varied from about $3 to $5 in volume. Although MAP feeds into a major market, the application is on the decline. Because of a desire for a more direct and accurate measurement technique, MAP sensors are being replaced by mass air flow (MAF) sensors, which provide a more direct control of the engine. The major drawback to MAF sensors at this point is their high cost (e.g., about $30 for the hot wire anemometer from Hitachi), a significantly higher price than for MAP sensors (<$5). Several micromachining options are being considered in an attempt to reduce the cost of an MAF sensor, but none has yet led to a promising approach. Bosch introduced a thin-film equivalent to a hot wire anemometer in 1995. Several organizations are searching for a MEMS version of such a thin-film anemometer. In MAF-based systems, the MAF sensor replaces the MAP sensor in conjunction with a BAP sensor needed to correct for altitude. These BAP sensors are often identical to MAP sensors. Obviously, losing the MAP sensor application does not mean losing all the pressure sensor applications in engine control. In Figure 10.23, we illustrate the Bosch BAP sensor mounted in a premold housing.

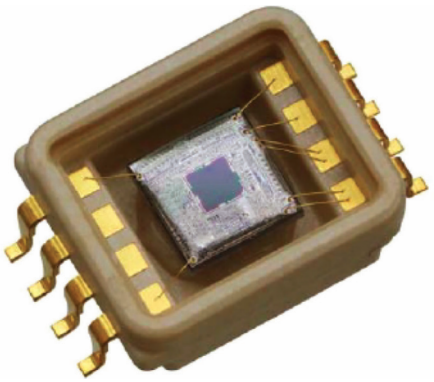

FIGURE 10.23 A barometric air pressure sensor in a premold housing by Bosch Sensortec.

Tire Pressure Monitoring Systems

One of the fastest growing new applications of MEMS pressure sensors is in Tire Pressure Monitoring Systems (TPMS). The U.S. Department of Transportation's National Highway Traffic Safety Administration (NHTSA) has mandated a new safety standard to warn the driver when a tire is significantly underinflated. The mandate required manufacturers to install a four-tire TPMS that is capable of detecting when a tire is more than 25% underinflated and warning the driver (mandated compliance of 100% for passenger cars was in September 2007). This mandate had its origin in 2001, with a series of tire problems experienced by Firestone/Ford (100 accidents). Two TPMS types are available. The first is based on an indirect measurement: slight changes in wheel diameter in response to pressure loss are detected and computed by the changes based on wheel speed measurements provided by the antilock braking system (ABS). The second type of system is based on direct measurement with a pressure sensor, motion switch, and wireless transmitter installed in the tire's valve stem or wheel to make the measurement (Figure 10.24). The sensor sends information on inflation pressure levels by radio signals to a receiving unit inside the vehicle and a dashboard indicator alerts the driver. The direct method is considered to be more accurate than the indirect approach, but the advantage of greater accuracy is offset by a cost of $65 to $80 per vehicle, since a market-friendly price for a system consisting of a pressure sensor, electronics, and a wireless transmitter is $12–$15 per wheel. High-volume manufacturing should reduced the price to below $10. Sixty million TPMS units were expected in 2008 for the U.S. market alone.

Whereas the TPMS technology today involves a unit mounted in the wheel powered by a battery, in the near future we will see the arrival of the intelligent tire. In this case the TPMS unit will be mounted in the tire itself instead of on the wheel. This will represent a tremendous market opportunity: from 2010 onward, 200 million tires per year were expected on new cars and a 1 billion per year replacement tire market (two or three sets in lifetime). By that time, it was anticipated tires would feature an embedded battery-less pressure sensor/wire antenna for continuous monitoring, and additional data on wear and traction [feed data for the electronic stability program (ESP)] will be available. Interestingly, in this scenario the responsibility for safety of the passenger will shift from car to tire manufacturer.

WTC estimated that the market for TPMS systems would grow at 50% in 2008 due to the U.S. mandate described above before leveling off in 2009–2010 to a growth rate of under 10%. Technology options are resistive and capacitive pressure sensors and SAW devices. Infineon/Sensonor and GE Novasensor are the traditional leading MEMS sensor manufacturers for this application. Whereas two companies were competing in this market in 2005 (Infineon/Sensonor and GE Novasensor), as of 2008, fifteen companies had products available. Other players are

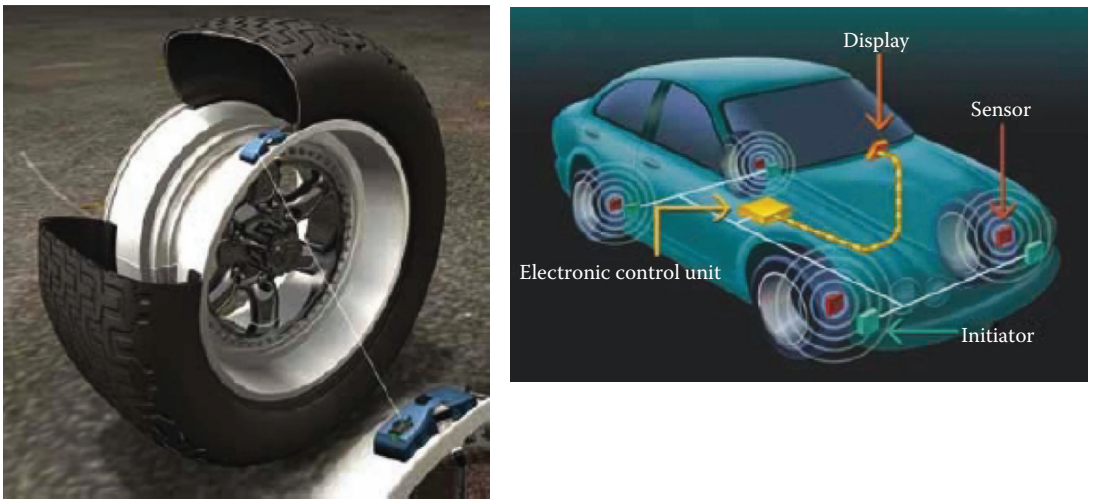

FIGURE 10.24 Microelectromechanical system pressure sensor with wireless data transfer in rim of tire.

TI, Freescale, Bosch, Melexis. Kavlico, Continental, Schraeder, Siemens VDO, and Philips (not the sensor chip). Many other companies have products under development (e.g., at LVsensors, http://www.lvsensors.com).

Important future automotive pressure sensor developments include high-pressure sensors, such as those required for cylinder pressure sensors (one per cylinder). The latter will be required for direct pressure determination inside the combustion chamber, starting with diesel engines. Lower emissions and improved fuel economy are expected to justify the higher cost. The extreme pressure rules out silicon, and in-cylinder sensors may alleviate the need for MAP and air intake MAF devices altogether. Honeywell has licensed fiber-optic pressure sensing technology for this demanding application.

Comparison of Manufacturing Approaches for Pressure Sensing

The majority of Si MEMS pressure sensor processes today are CMOS-compatible. About 55% of production is on 6-inch wafers, and this is expected to increase to 80% in 2010.[15] Manufacturing on 8-inch wafers is becoming more and more popular. It is expected that by 2011, 29% of MEMS manufacturing will be on 8-inch wafers. In 2007, Omron, Freescale, Silex, and DNP all announced new investments in 8-inch manufacturing. The pressure sensors market in the automotive world is under tremendous pressure to reduce cost. Several manufacturers have set up their production centers in Asia Pacific regions because of the lower production and labor costs.

The manufacturing approach for pressure sensing and, to some extent, for all Si micromachined sensors for large industrial market applications where cost is the main issue must incorporate as many of the following attributes as possible:

- CMOS compatibility because of the increasing demand for digital-compatible (see also resonant beam approach, described below), highly integrated Si smart sensors
- Six-inch compatible because of IC trend/availability (and 8-inch silicon MEMS is coming up fast)
- As little fixturing as possible
- Al- (in the future, this might become Cu instead) and IC-line-compatible etchants
- Generic, making it easy to implement a different sensing range or different package or even a different sensor type
- Highest accuracy potential (favors capacitive and resonant devices; see below)
- Wafer-level isolation of electrical connections, making it easier to use in harsh media (removing sensor metallization from the media themselves)
- Dry etching whenever possible
- Single-sided processing if feasible

Polysilicon now holds the cost advantage over a silicon-on-insulator (SOI) approach, but polysilicon will not readily lead to a high accuracy method. Like SOI, bulk micromachining constitutes a more secure option to meet the accuracy demands of future pressure sensor generations but often involves too many glass and/or Si wafers stacked up in one device to allow for an economic solution. Moreover, bulk micromachining is a more expensive technology and up to recently less CMOS compatible than polysilicon. We say up to recently, since Bosch succeeded in making bulk micromachining more CMOS compatible [see the Bosch advanced porous silicon membrane (APSM) process in Volume II, Chapter 4, (Figure 4.77)]. SOI might be able to compete better with polysilicon, as clever designs could obviate the complicated multiple wafer solutions that characterize today's bulk micromachining stacks for pressure, acceleration, and gyros (a three- to five-wafer stack design is not uncommon). SOI technology will also become more and more available and less expensive as it becomes more commonly used in the IC industry. We believe that the SOI approach will become a competitive technology for low-cost, high-accuracy sensors without the reproducibility and long-term stability issues of the polysilicon material.

SOI wafers are finding increasing applications for pressure sensor devices, especially for industrial applications. Most pressure sensors still are bulk micromachined, so wet etching remains a key process. Packaging is a large part of the component cost, and wafer bonding for wafer-level packaging (WLP)

is a growing trend (see Chapter 4, this volume, on packaging, assembly, and self-assembly).

We can summarize that, for now, an inexpensive solution for a pressure sensor with moderate accuracy is based on polysilicon. In the long run, a single-crystal approach based on the Bosch APSM process or an SOI approach, perhaps with a resonant design (see next), is more suited for a generic strategy to produce higher accuracy devices.

Piezoresistive, Capacitive, Resonant Beam, and Other Sensor Approaches

Introduction

The arguments we present in this section about what sensor mechanism to choose for a given pressure sensor application pertain equally well to accelerometers and angular rate sensors. The impetus for obtaining higher accuracy and sensitivity in automotive sensors usually hinges on energy efficiency and/or regulatory mandates. This may require a review of the transducing methods, currently still dominated by piezoresistivity. Examples of alternatives include optical techniques such as Honeywell's in-cylinder fiber-optic pressure sensor, the significantly higher sensitivity of both capacitive and resonant approaches, piezoelectric sensing (mainly for high frequency applications), and tunneling current sensing (very sensitive but increased complexity). The inherent digital compatibility of resonant beams may propel them to the foreground for high accuracy and very low-signal sensor applications. Because of the promise held by the resonant sensing application, we detail this technology a bit further here.

Resonant Beam Sensors

Electrical readout in a pressure sensor, an accelerometer, or angular rate sensor may be performed using piezoresistors located in a flexure area, by measuring the change in capacitance of the moving members with respect to the fixed member(s), or by the measurement of frequency change of a small resonant structure. A resonator is a mechanical structure fabricated to vibrate at a particular resonant frequency. The resonant frequencies of such microresonators can be made extremely stable, so they are used as a time base (the quartz tuning fork in watches, for example) or as the sensing element of a resonant sensor. The performance benefits of a well-designed resonant sensor are compared with piezoresistive and capacitive techniques in Table 10.7.[17] A common advantage of resonant beam and piezoresistive is that they do not depend on measurements relative to "fixed" members, as the capacitive approach does. The small signal magnitude (small capacitance change ΔC) of a capacitive sensor means that on-chip electronics are mandatory to avoid errors due to stray capacitance variations. Piezoresistive and capacitive sensing elements must be used with high-precision amplifiers and trimmed analog circuits to accurately sense and condition small changes in the value of the electronic components. These sensitive circuits and small signals can be highly susceptible to fluctuations in temperature, electrical noise, mechanical and electrical drift, temperature and pressure cycling hysteresis, ionizing radiation, and magnetic fields. These factors and others result in measurement inaccuracies, effectively degrading overall precision and resolution. As a result, best-case production performance of solid-state sensors generally has been limited to a long-term accuracy of about 0.1%, or 1000 ppm.

Resonating devices, on the other hand, are affected primarily by the mechanical characteristics of the structure, not by its electrical behavior. In addition, since the system itself measures only frequency, the interface to a digital system vastly is simplified. In practice, resonant sensors can attain measurement accuracies at least 10 times higher than conventional sensing methods. The fabrication of resonant structures, however, is more complex, and the requirement for packaging such devices more demanding than for piezoresistive or capacitive sensors.

The basic building blocks for a resonant beam structure embedded in a pressure-sensitive membrane are shown in Figure 10.25.[18]

The specific structure shown here is one by the Yokogawa Corporation. To operate as a differential pressure sensing device, this chip incorporates two H-shaped bridges, located in the Si substrate and operating at the same identical frequency (90 kHz). Both bridges (resonators) are located at the same strain-free plane (depth) from the chip's surface, but in different locations. A resonant sensor is designed

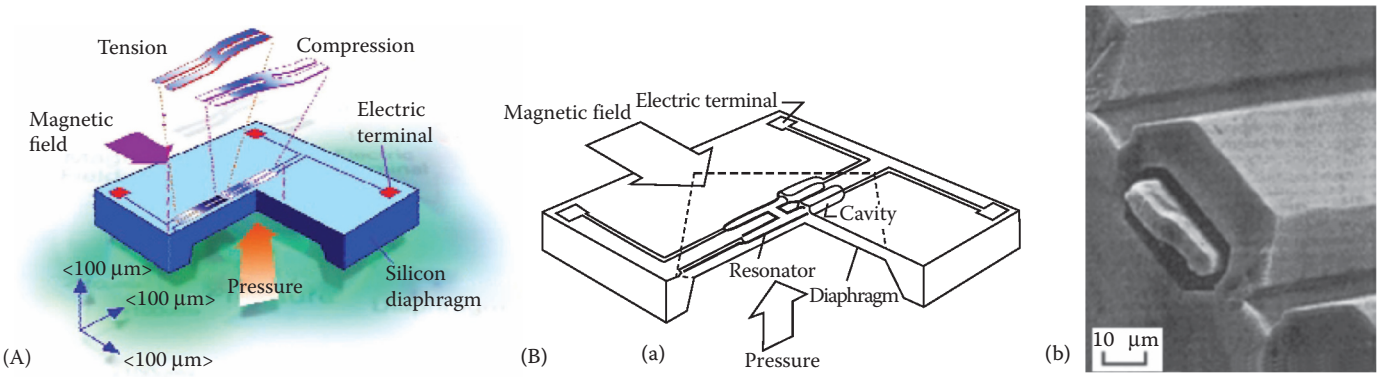

FIGURE 10.25 (A) Digital sensor technology by Yokogawa Corporation. (B) Construction of the sensor (a) and cross-sectional scanning electron microscope photograph of the resonator (b).[18]

such that the resonator's natural frequency is a function of the measurand (pressure in this case), and typically the measurand alters the stiffness, mass, or shape of the resonator, hence causing a change in its resonant frequency. In the current case, when pressure is applied, because of their position and exact depth in the substrate, one bridge goes into tension and the other into compression. The other important features of a resonant sensor are the vibration drive and detection mechanisms. The Yokogawa chip incorporates an electromagnetically driven resonant beam sealed in a vacuum shell, integrated onto a standard silicon pressure sensor diaphragm (an SOI approach is used). The drive mechanism excites the vibrations in the structure while the detection mechanism senses these vibrations. The frequency of the detected vibration forms the output of the resonant device. As pressure is applied the compression bridge changes from 90 to 110 kHz and the tension bridge from 90 to 70 kHz. To obtain a differential output the microprocessor simply counts the change in bridge frequencies (Δ40 kHz). In the case of gauge pressure measurement, both bridges are used. One bridge measures the reference pressure (atmospheric or head pressure), and the other one measures the applied pressure (gauge).

With the digital pressure sensor pictured in Figure 10.26, it was demonstrated that an accuracy of 0.01%, or 100 ppm, is attainable. The device also offers wide dynamic range, high sensitivity, and high stability, along with a frequency output for easy interface to digital compensation circuitry. The chip fabrication is challenging though, comprising four sequential selective epitaxial growth and critical selective etching steps, and the sensor package is extremely complex and therefore expensive to produce. It is, nonetheless, an excellent example of the power of silicon microfabrication technology

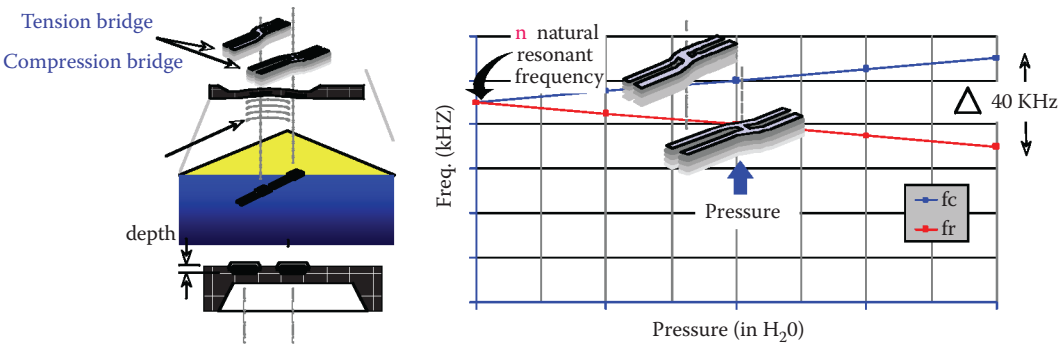

FIGURE 10.26 Operating principle of the digital pressure sensor. The first bridge is located directly in the center of the chip and the other nearer the edge. As pressure is applied, the center bridge will be in a state of "compression" and the outer bridge in a state of "tension." As a result, the natural frequency of the two bridges changes. The compression bridge frequency increases and the tension bridge frequency decreases, thereby effectively creating a differential frequency. The two frequencies are easily managed by a CPU as a time-based calculation directly proportional to the applied differential pressure. (From Yokogawa Corporation of America.)

and represents a major technical achievement. Morover, Yokogawa's application represents the industrial sensing and control business, which is aimed at high-performance sensors that can sell for higher prices in modest volumes.

GE Druck also developed and incorporated a resonant silicon sensor in its pressure transducers (http://www.gesensing.com/druckproducts), as well as GE NovaSensor.[19] Zook et al.[20] fabricated clamped-clamped beams in a polysilicon surface micromachining process and, by locating the polysilicon beam in a high-vacuum polysilicon shell, avoided damping. Surface micromaching simplified the manufacturing process over previous attempts in SOI by Ikeda et al. shown in Figures 10.25 and 10.26[21] and may be able to produce cost-effective resonators as replacements for piezoresistors. The sensitivity to applied axial loads of the beam exceeds the gage factor of single-crystal piezoresistors easily by a factor of 10–100. Devices with sensitivities as high as 700 Hz/g have been reported.[22]

Today, the resonant beam approach remains the least-developed sensing mode, despite the fact that the resonant beam method showed very good potential in the past (although expensive and difficult to implement). So it is interesting that there is not more commercial activity to validate this sensing approach further and making these resonant sensing devices less expensive. It could be that one of the main reasons why direct frequency sensing is not investigated more is the fabulous resolution ADI achieved with its capacitive sensing scheme. Because the signal conditioning is so tightly coupled to the sensing element, the integrated ADI sensors can measure extremely small changes in differential capacitance. As an example, the capacitance resolution of their inexpensive ADXL202E, a surface-micromachined 50-mm^3 accelerometer, is as low as 20 zeptofarads (20×10^{-21} F) (see next section).

Accelerometers

Introduction and Market Perspectives: Victim of Success

WTC estimated that in 2006, the silicon-MEMS market in the automotive sector was $1.6 billion (this firm only counted flow, pressure, acceleration, and rate),

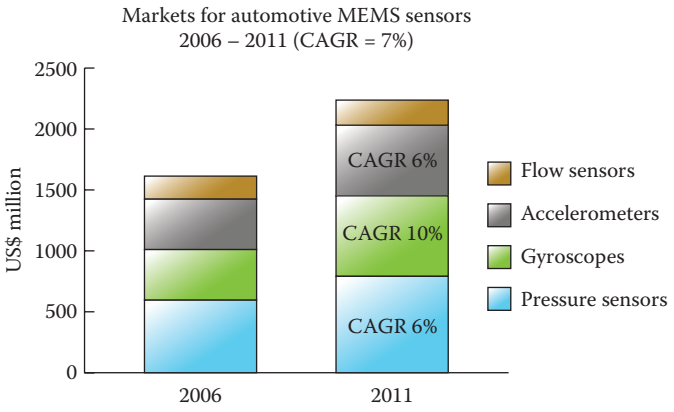

FIGURE 10.27 Markets for automotive microelectromechanical system sensors, according to WTC.

making this the second biggest MEMS opportunity after RW-heads and ink-jet print heads. By 2011, the same market was pegged at $2.2 billion, with a CAGR of around 7%. The main applications in revenue terms were, in order, pressure sensors, gyroscopes, accelerometers, and flow sensors, as shown in Figure 10.27.

The total number of Si sensors WTC claimed would grow from over 430 million units in 2006 to 780 million in 2011, an annual growth of 13% (for a reference point, consider that by 2006, Bosch had produced 600 million sensors, 130 million units in 2006 alone). This outstrips the dollar growth because of price erosion, running at 4–5% per year.

Yole estimated the 2005 worldwide accelerometer market at $393 million, representing about 8% of the overall silicon-MEMS market. By 2010, they expected the accelerometer market to be $869 million, for a five-year CAGR of 17%.

Major players in this space include Bosch, Infineon, ADI, Denso, and Delphi. Since the early 2000s, manufacturers have been putting accelerometers in consumer electronics such as laptops [it started when IBM (now Lenovo) put a dual-axis accelerometer in its notebook in 2004], cameras, and cell phones. WTC fears that in coming years the accelerometer market will suffer from price pressures reminiscent of that in consumer electronics (10% per year). Accelerometers might become victims of their success!

Accelerometers signified the next big Si micromachining entry in the commercial world after the Si pressure sensor. Today, polysilicon surface-micromachined capacitive and single-crystal Si bulk-micromachined accelerometers have taking over a

large share of the automotive acceleration market. Manufacturing volumes of tens of millions a year have brought down the price to less than $2 per sensor. A company such as ADI makes 2 million surface-micromachined accelerometers a week.

A major difference between accelerometers and pressure sensors in cars is that less diverse types of accelerometers are needed. Pressure sensors require various ranges and many different packages to accommodate the sensors in their unique environments. Accelerometers, on the other hand, require little difference in packaging; two main types (i.e., high *g* and low *g*) cover all needs. This explains why the first surface-micromachined commercial Si sensor was an accelerometer rather than a pressure sensor.

The first demonstration of a capacitive Si micromachined accelerometer took place in 1979 at Stanford University.[4] Over the years, a variety of accelerometers based on different physical detection schemes, such as piezoelectric, piezoresistive (thin- and thick-film), capacitive, tunneling, and resonant members, have been attempted in a wide variety of manufacturing schemes. As listed in Table 10.4, in cars, accelerometers are used as crash detection sensors both in the electronic control unit (ECU) and in peripheral sensors such as upfront sensors (UFS) or pedestrian contact sensors close to the bumper, peripheral acceleration sensors (PAS) in the doors, and rear crash sensors.

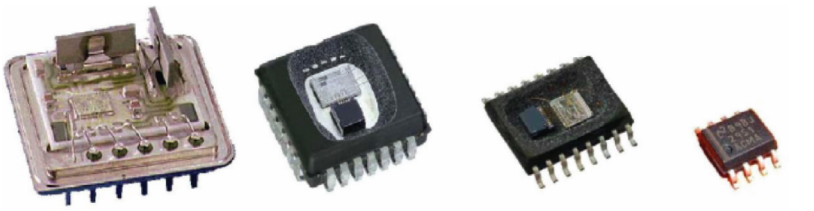
Automotive Accelerometer Examples

Airbag Accelerometer

The principal mass market for Si acceleration sensors in the automotive industry is in crash detection and airbag release systems. A MEMS-based accelerometer detects with great precision the sudden slowing of a vehicle and fires the airbag when needed. Now produced in the millions per year, these devices have gotten smaller, cheaper, and more capable, riding the learning curve originally promised by MEMS proponents. This learning experience by Bosch-Sensortec is illustrated in Figure 10.28 as a sequence of product generations for automobile airbag systems introduced over time. The MEMS elements are not only getting much smaller than the formerly used fine-mechanical piezoelectric device (shown in Fig. 10.28a) but also much more cost efficient, and yet they include an increasing number of functions (such as self-tests and accuracy check routines).

In 1991, the Intermodal Surface Transportation Efficiency Act (ISTEA) was signed into law. ISTEA airbag requirements ensured that by 1998, 100% of the new U.S. vehicle fleet be equipped with airbags. System integrators like Autoliv expect airbag accelerometer penetration to increase from 40 to 60 million vehicles over the five-year period between 2006 and 2011 (i.e., 80% of cars worldwide). WTC estimated that this penetration equals an insertion of 200 million accelerometers in 2006 going up to 350 million in five years, with as many as eight accelerometers per electric control unit (ECU).

An earlier generation of airbag sensors used in the United States consisted of electromechanical types supplied by Breed and TRW (see Table 10.5). Three electromechanical accelerometers discriminated between zones according to the severity of a vehicle crash. Two sensors were used in the crush zone, usually on frame rails behind the front bumpers or on the lower portion of radiator supports. These sensors determined the severity of impact and activation of the airbag.



1984 – 1997	1997 –	2002 –	Coming soon
Hybrid piezoelectric	Silicon micromachined capactive	Silicon micromachined capactive	
(a)	(b)	(c)	(d)

FIGURE 10.28 Generations of high-*g* acceleration sensors used in automotive airbag systems at Bosch.

Another sensor was located outside the crush zone, either in or near the passenger compartment. This sensor, often known as the *safing sensor*, prevented deployment of the airbag in the event someone inadvertently impacted (or tampered with) the front sensors.

Micromachined accelerometers displaced these electromechanical devices, as they made single-point sensing possible. Single-point sensing requires only one accelerometer, located in the passenger compartment, reducing the number of sensors and associated wiring needed in the system. In addition to reducing the number of sensors required in each system, surface-micromachined accelerometers from ADI were costing approximately $4 per unit in volume in 1998 (and below $2 today), significantly less than electromechanical accelerometers at approximately $15 per unit.

The early bulk-micromachined Si accelerometers lacked damping and overload protection until TRW NovaSensor introduced a piezoresistive accelerometer combining a microactuator for reliable self-testing and overload protection on the same chip. This Si bulk-micromachined ±50-*g* accelerometer based on hybrid technology, with signal conditioning electronics on a separate chip, bonded into a TO-5 header, is shown in Chapter 4, this volume, Figure 4.9.[23] In 1991, ADI introduced the first commercial product to use polysilicon surface micromachining, the so-called *ADXL-50*, a capacitive accelerometer with an electrostatic actuator built in for self-testing. The construction of this sensor was studied in Volume II, Example 7.9 (see also Volume II, Figures 7.92–7.96).

More and more vehicles are being equipped with side airbags, ensuring continued growth of the accelerometer market. Primarily ADI, GM/Delco, and Motorola supply silicon accelerometers in the 50-*g* range for U.S. vehicles. Sensonor (Norway) has historically provided a large portion of the European market, while Nippondenso is the major provider in Japan. The ADI accelerometer was the first integrated sensor; most other accelerometers on the market still use a multichip solution to sense and provide the appropriate signal condition.

Suspension Accelerometers

ADI, between 1990 and 2000, branched out from their high-*g* range of airbag (50 *g*) accelerometers, to medium and low-*g* sensors for suspension and stability control devices (say, 0–2 *g*).

Silicon accelerometers in suspension systems face more hurdles than the Si accelerometers in airbag systems. Low *g* is more difficult (signal-to-noise limit), signal conditioning is required with each remotely mounted package (one suspension sensor per wheel), and the sensor is exposed to the harsh automotive environment, i.e., more complex packaging. Many companies, including ADI and Motorola were and still are aggressively pursuing this application. Low-*g* accelerometers are also of utility in antilock braking systems (ABS) featuring traction control. No federal law mandates ABS/traction control, and because of the cost constraints, only high-end and midsize cars are expected to utilize the system.

In 1995, using its patented iMEMS® (integrated MEMS) approach, ADI introduced a 5-*g* accelerometer, pushing the polysilicon surface micromachining technology it pioneered with their 50-*g* device (the ADXL50) a bit further. Also out of ADI, in 1998, came the breakthrough 2-*g* dual-axis ADXL202E accelerometer, an inexpensive, surface-micromachined accelerometer capable of measuring both static (gravitational force) and dynamic (vibration and shock) forces, pushing the surface micromachining sensor technology even further. This sensor detects movements on two axes and outputs digital signals to microcontrollers as simple as 4-bit microcontroller units (MCUs). A single moving "beam" in the ADXL202E has "fingers" that are used to detect beam movement (through capacitance change) in two directions, and this goes through an on-chip algorithm and is sent along as digital data. In Figure 10.29a we show how silicon is used to make the spring and proof mass and how a finger is added to make a variable differential capacitor. The beam is made up of many interdigitated fingers, and each finger can be visualized as shown in this figure. The electronics measure the change in displacement by measuring the change in differential capacitance against a set of fixed fingers (plates). The critical dimensions of fingers and the proof mass (0.7 μg) of this sensor are clarified in Figure 10.29b. The finger height (2 μm for the example product) is fixed by process technology, while the overlap (125 μm here) is adjustable to

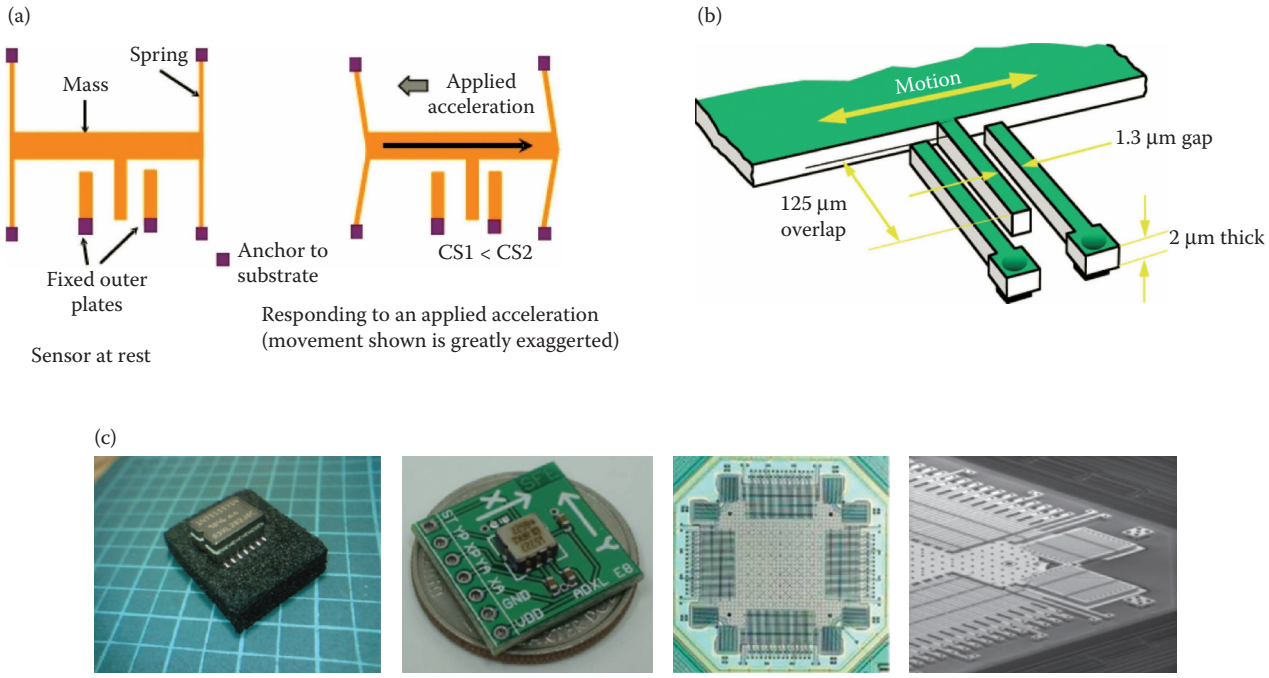


FIGURE 10.29 Analog Devices' ± 2 *g* dual-axis ADXL202E accelerometer is an inexpensive, surface-micromachined accelerometer capable of measuring both static (gravitational force) and dynamic (vibration and shock). (a) Silicon is used to make the spring and proof mass, and fingers are added to make a variable differential capacitor. (b) Critical dimensions and proof mass weight and dimensions for a single finger. The proof mass is 0.7 µg. The accelerometer has some impressive numbers: 0.1 pF per side for the differential capacitor, 20 zF (10^{-21} F) smallest detectable capacitance change, and 2.5 pm minimum detectable beam deflection (one tenth of an atomic diameter). (c) In the ADXL202 beam structure, note the four pairs of orthogonal serpentine springs at the corners of the proof mass. The entire mechanical structure is suspended from the four points where the springs meet.

some extent. Longer fingers are not desirable, because they are harder to manufacture and result in larger beam areas, which in turn translates to more expensive sensors. The fingers are released when the oxide layer between the underlying bipolar IC and the beam is etched away, leaving a 1.6-µm gap with fingers spaced every 1.3 µm. Rather than using two discrete beams placed orthogonally, the fingers that constitute the *x*- and *y*-axes, variable capacitors are integrated along the sides of a single square beam. This results in a reduction of the overall sensor area, yet the larger common beam mass enhances the resolution of the ADXL202E. The differential capacitance of each finger is proportional to the overlapping area between the fixed outer plates and the displacement of the moving finger. Because these are very small capacitors, one needs the largest practical differential capacitance to reduce noise and increase resolution. The fixed outer plates are driven with square waves that are 180 degrees out of phase. When the movable fingers (and hence the beam) are centered between the fixed outer plates, both sides of the differential capacitor have equal capacitance and the AC voltage on the beam is zero. However, if the beam is displaced due to an applied acceleration, the differential capacitance will be unbalanced, and an AC voltage of amplitude proportional to the displacement of the beam results. In this sensor movements as minute as 0.02 Å are detectable. Because of the combination of low cost and high performance acceleration/tilt sensing possible with this device, other applications have become possible. The ADXL202E is currently used in car alarms (for jacking or towing sensing), pen-based handwriting recognition systems, portable electronic games, and wearable sports equipment.

The ADXL202E was an early demonstration that there is a path for MEMS from automotive applications to consumer electronics. The average price of MEMS accelerometers across all applications is decreasing, from an average of $2.50 in 2004 to less than $1.90 in 2009, with consumer applications driving the price erosion. The average selling price (ASP) for a three-axis MEMS accelerometer was still

approximately $2.00 in consumer products in 2006, while lowest cost products were already shipping at under $1.50 in 2006. It was expected that by 2009, the average selling price would drop to $1.35, and the least expensive (first-level packaged) three-axis accelerometers would ship for under $1.00.

Comparing Manufacturing Options for Accelerometers

In the automotive market 80% of accelerometers are manufactured using deep reactive ion etch (DRIE) equipment. Growth in the accelerometer market overall actually is driving growth of DRIE equipment sales. The primary wafer size for accelerometers is currently 6-inch (accounting for more than 80% of device production), but 8-inch wafers are expected to make inroads and were projected to account for nearly 10% of production by 2010. Devices are typically processed on silicon, with SOI wafers in use or in development by the major manufacturers.

Obtaining sufficient sensitivity was originally thought to be a potential problem when using polysilicon to manufacture low-*g* accelerometers. To make a large proof mass is especially challenging for polysilicon accelerometers. Process control and handling considerations limit the minimum flexure thickness for suspending the inertial mass to about 2 µm and, given the relatively low density of Si, obtaining deflection at 1 or 2 *g* without making the proof mass large is difficult. Realizing a large proof mass directly affects chip size and thus cost, presenting the developer with an unattractive option. The proof mass of a bulk-micromachined accelerometer may be 0.1 mg, whereas a typical value for a surface-micromachined device is 0.5 µg, 200 times smaller. With a source capacitance in the neighborhood of 150 femtofarads (i.e., 0.15 pF), and orders of magnitude smaller differential capacitance changes, say 100 attofarads (10^{-18} F) for a 1-*g* acceleration, a resolution of 23 zeptofarads (10^{-21} F) is required, and the signal output of these devices easily could be lost in the presence of parasitic capacitance or noise. Despite these early misgivings expressed here, the surface-micromachined ±2-*g* capacitive accelerometer announced in 1995 by ADI demonstrates that low-*g* polysilicon sensors and cost-effective integration of all the electronics is quite possible. It is actually within ADI's abilities to provide on-chip signal conditioning that allows the minute signals to be read with minimal interference. A synchronous demodulation technique ("AC bridge") is used to increase noise immunity and improve the signal to noise ratio. A square-wave carrier drives the sensor, and the modulated signal produced by the change in differential capacitance is amplified and synchronously demodulated, minimizing noise and boosting the signal-to-noise ratio.

In silicon bulk-micromachined accelerometers, the formation of a mesa structure (proof mass) from a single crystal Si is more complicated because of rapid and irregular etching of convex corners by orientation-dependent etchants, such as ethylene diamine pyrocatechol (EDP) and KOH. Corner compensation schemes must be invoked to avoid irregular corners (see Volume II, Chapter 4).

Critics of the capacitive polysilicon accelerometer still maintain that the integration of electronics is too complex and that a bulk-micromachined sensor requires only twelve mask levels, whereas the polysilicon device requires twenty-eight mask levels. Along this line, major Japanese companies have chosen single-crystal solutions for building accelerometers to avoid the difficulties associated with reproducing polysilicon material properties and the possible unknown long-term instabilities.

The pros and cons of surface micromachining (see Volume II, Chapter 7) can then be summarized as follows:

Pros

- A surface-micromachined device has a built-in support, resulting in cost effectiveness.
- Surface micromachining only requires one-sided processing compatible with conventional IC processes.
- Devices made by surface micromachining are smaller in size, have higher yields, and accommodate more on-chip circuitry.

Cons

- The out-of-plane dimensions in surface micromachining in general is limited to ~2 µm, hence the light mass of the proof mass, resulting in a low sensor sensitivity.

- The suspended Si structure is more compliant (due to the high ratio of length to thickness of the device structure) and hence has a tendency to stick to the support substrate, especially in overdrive situations.

As we made clear in the section on pressure sensing, we believe that SOI surface micromachining combines the best features of surface micromachining with the best features of single-crystalline Si. The same benefit befalls the Bosch IMAPS process, which enables electronic integrations just as in the case of ADI (see above). Using dry etching to etch the proof mass from an epimaterial avoids corner compensation issues; the epimaterial ensures larger mass and single-crystal performance. This approach might overtake both surface and bulk micromachining as SOI wafers become less expensive and more available. A generic design of a resonant beam structure in an SOI wafer may be possible. This design could constitute the basis of a wide family of pressure, acceleration, and angular rate sensors.

MEMS Angular Rate Sensors

Introduction

First, some clarifications are in order about the definitions of an angular rate sensor, gyros, and accelerometers. An angular rate sensor is not a gyro, but it is common jargon to refer to an angular rate sensor as an *electronic gyro* or even simply a *gyro*. In reality they are quite different, although one can be made to act like the other. Angular rate sensors measure angular rate (surprise!), i.e., how fast (degrees per second or radians per second) something is rotating. A gyroscope, on the other hand, is used to measure angular position (not rate), using the principle of "rigidity in space" of the gyroscope (see Figure 10.30). For example, this is how the attitude indicator (artificial horizon) of an aircraft works. A gyroscope can be made to measure angular rate (using the principle of precession), but that requires a finely calibrated measuring spring. Conversely, an angular rate sensor can be made to measure angular position by integrating the signal over time. So, an angular rate sensor can be made to act like a gyro, and a gyro can be made to act like an angular rate sensor, but they do not act the same by themselves. Lastly, an accelerometer is nothing like a gyro and cannot be made to act like one. An accelerometer measures linear acceleration. Using calculus, this can be integrated into linear velocity and position. The rotation typically is measured in reference to one of three axes: yaw, pitch, or roll (see Figure 10.30). The difference between an accelerometer and an angular rate sensor is that the gyro measures the angular acceleration (how fast the rate is at which an object rotates changes) and the accelerometer measures how much something is accelerating (not angular).

As an example of how an angular rate sensor could be used, a yaw-axis angular rate sensor that is mounted on a turntable rotating at 33 1/3 rpm (revolutions per minute) would read a constant rotation of 360° times 33 1/3 rpm divided by 60 seconds, or 200°/s. In the case of an electronic angular rate sensor, a voltage proportional to the angular rate, as determined by its sensitivity, measured in millivolts per degree per s (mV/°/s), would be the output. The full-scale voltage range determines how much angular rate can

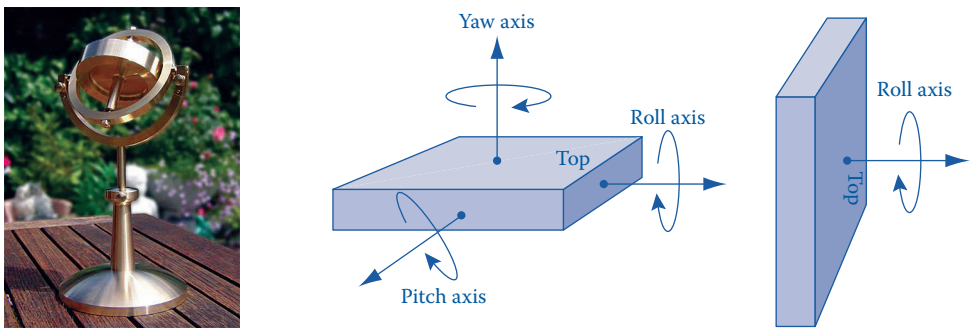

FIGURE 10.30 Illustration of a conventional mechanical gyroscope and the three rotational degrees of freedom it can measure (http://www.brassgoggles.co.uk/images/brassgyroscope.jpg). Shown are gyro axes of rotational sensitivity. Depending on how a gyro normally sits, its primary axis of sensitivity can be one of the three axes of motion: yaw, pitch, or roll (see also Figure 10.31).

be measured. In the turntable example, an angular rate sensor would need to accommodate a full-scale voltage corresponding to at least 200°/s. The full-scale range is limited by the available voltage swing divided by the sensitivity. The ADI MEMS angular rate sensor we will analyze below, the ADXRS300, comes with 1.5 V full-scale and a sensitivity of 5 mV/°/s, so it handles a full-scale of 300°/s. One practical application of an angular rate sensor is to measure how quickly a car is turning. If the angular rate sensor, mounted in the car, senses that the car is spinning out of control, differential braking engages to bring it back into control. As we saw earlier, the angular rate signal can also be integrated over time to determine angular position particularly useful for maintaining continuity of GPS-based navigation when the satellite signal is lost for short periods of time, for instance, when the car is in a tunnel.

Before satellite-based global positioning systems (GPSs), there was the mechanical gyroscope: a reliable rotation sensor, based on the inertial properties of a rapidly spinning rotor. This mechanical contraption, which has been around since the late 1700s, is used for maintaining a fixed orientation with great accuracy regardless of the earth's rotation, as shown in Figure 10.30. Traditional spinning gyroscopes work on the basis that a spinning object that is tilted perpendicularly to the direction of the spin will have a precession. The precession keeps the device oriented in a vertical direction so that the angle relative to the reference surface can be measured. A rotation in the frame thus imparts a torque (rotation) on the spinning disk, which precesses (rotates) as a result (conservation of angular momentum). In other words, the flywheel's large angular momentum counteracts externally applied torques and keeps the orientation of the spin-axle fixed. Practical applications limit the movement to measure only one axis of rotation (roll, pitch, or yaw; see Figure 10.30). Precision-machined mechanical gyros may cost anywhere between $10,000 and $100,000.

The ring-laser gyroscope, first discussed by Georges Sagnac (1869–1926) in 1913 and demonstrated in 1962 by Warren Macek of Sperry Corporation, quickly displaced mechanical versions for high-end and high-precision applications such as aviation and is now even used in high-end cars. Sagnac discovered that light sent around a closed loop, in two different directions, would show a phase difference between the two beams when the loop is rotated (refer here to the discussion of the Michelson-Morley experiment in Volume I, Chapter 5, "The Lorentz Transformation"). The Sagnac effect is illustrated in Figure 10.31. The ring-laser gyroscope consists of two laser beams traveling in opposite directions (i.e., counter-propagating) around a closed-loop path. The pulse traveling in the same direction as the rotation of the loop must travel a slightly greater distance than the pulse traveling in the opposite direction. As a result, the counter-rotating pulse arrives at

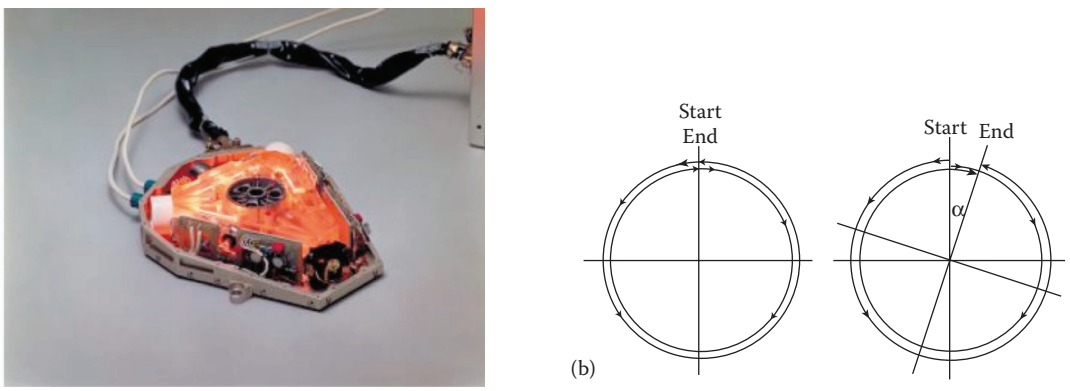

FIGURE 10.31 (a) The RLG. (b) The Sagnac effect: if two pulses of light are sent in opposite directions around a stationary circular loop of radius *R*, they will travel the same inertial distance at the same speed, so they will arrive at the end point simultaneously. This is illustrated in the left-hand drawing. The drawing on the right indicates what happens if the loop itself is rotating during this procedure. The symbol α denotes the angular displacement of the loop during the time required for the pulses to travel once around the loop. For any positive value of α, the pulse traveling in the same direction as the rotation of the loop must travel a slightly greater distance than the pulse traveling in the opposite direction. As a result, the counter-rotating pulse arrives at the "end" point slightly earlier than the corotating pulse.

the "end" point slightly earlier than the co-rotating pulse. The constructive and destructive interference patterns formed by splitting off and mixing parts of the two beams can be used to determine the rate and direction of rotation of the device itself.

The fiber optic gyroscope (FOG) is based on the Sagnac effect and consists of a loop of single-mode optical fiber (often a polarization-maintaining fiber) and related coupler components, a semiconductor laser or superluminescent LED, and signal-processing electronics. The coupler components generally are fabricated in proton-exchanged $LiNbO_3$ integrated-optic circuits. This material is chosen for its ability to modulate the light beam for improved detection. The FOG, being a simpler device, currently is receiving more attention due to its potential to achieve the required performance at a lower cost than with ring laser gyroscopes (RLG) or mechanical gyroscope technology.

These instruments still cost about $1000. For example, the fiber optic gyro from Andrew Corp. (now KVH Industries) costs $950. It is a cylindrical device that measures 77 mm in diameter and is 88 mm long. The higher-end Honeywell Ring Laser Gyro (RLG) has revolutionized the way the world navigates on land, sea, air, and space. It is highly reliable because it has virtually no moving parts, replacing spinning mass with spinning light.

Interferometric FOGs and MEMS angular rate sensors are changing the commercial landscape of gyros once again. We cover only MEMS gyroscopes (angular rate sensors really) here; they are constructed out of silicon (often SOI) and quartz, or they may be ceramic-based.

Market Perspectives

The requirements for inertial sensors, i.e., accelerometers and angular rate sensors, vary drastically depending on the applications they are intended for. Figures 10.32a and 10.32b give an overview of the main performance requirements for accelerometers and angular rate sensors, respectively, in various applications.

In the late 1990s, inexpensive, solid state, micromachined angular rate sensors became the Holy Grail for many micromachinists around the globe. The same companies that made a lot of headway in micromachined accelerometers, such as ADI, are also at the forefront of Si angular rate sensor development today.

In 2005, according to Yole, global MEMS-based angular rate sensors sales were $558 million, and they were expected to grow by a CAGR of 11% through 2010 to reach $930 million. MEMS gyroscopes are included in three automotive applications: Antirollover systems, global positioning system (GPS) navigation, and electronic stability control (ESC). These automotive applications represent more than 70% of the MEMS gyroscope market. ESC is a rapidly growing market as these systems could potentially reach 100% adoption in new cars shortly after 2010. Current navigation system designs use a combination of global positioning (GPS) and CD-ROM maps in addition to wheel rotation sensors and angular rate sensors, or magnetic compasses. Angular rate sensors enhance the accuracy of navigation instruments in situations where satellite reception is lost, as for example in tunnels, between tall buildings, and in mountainous terrain. The cost of current navigation systems is in the $200 to $800 range, and MEMS solutions are expected to reduce this cost further.

As in the case of accelerometers, once gyros make it big in the automotive markets, they also succeed in consumer electronics (CE). The sensor specifications in consumer electronics are much more relaxed than in the automotive application, but price erosion and product cycles are much faster than in the automotive field.

Five consumer applications integrate MEMS gyroscopes: camcorder stabilization, camera stabilization, cell phone stabilization, video games, and navigation for small electronics. In 2006, Nintendo Wii's motion sensing remote control gave, for the first time, public visibility to inertial MEMS. The new attractive human-machine interface in game controls such as the Wii is expected to penetrate the cell phone market as well. Five sensors are used to monitor orientation of the Segway scooter, sampled at 100 times/s. Sensors include MEMS angular rate sensors and liquid-filled tilt sensors.

According to Yole, quartz and ceramic substrates were estimated to account for 37% by volume of total gyroscope production in 2005. But most new gyroscope development programs were silicon-based, so this figure was expected to decrease to 28% in

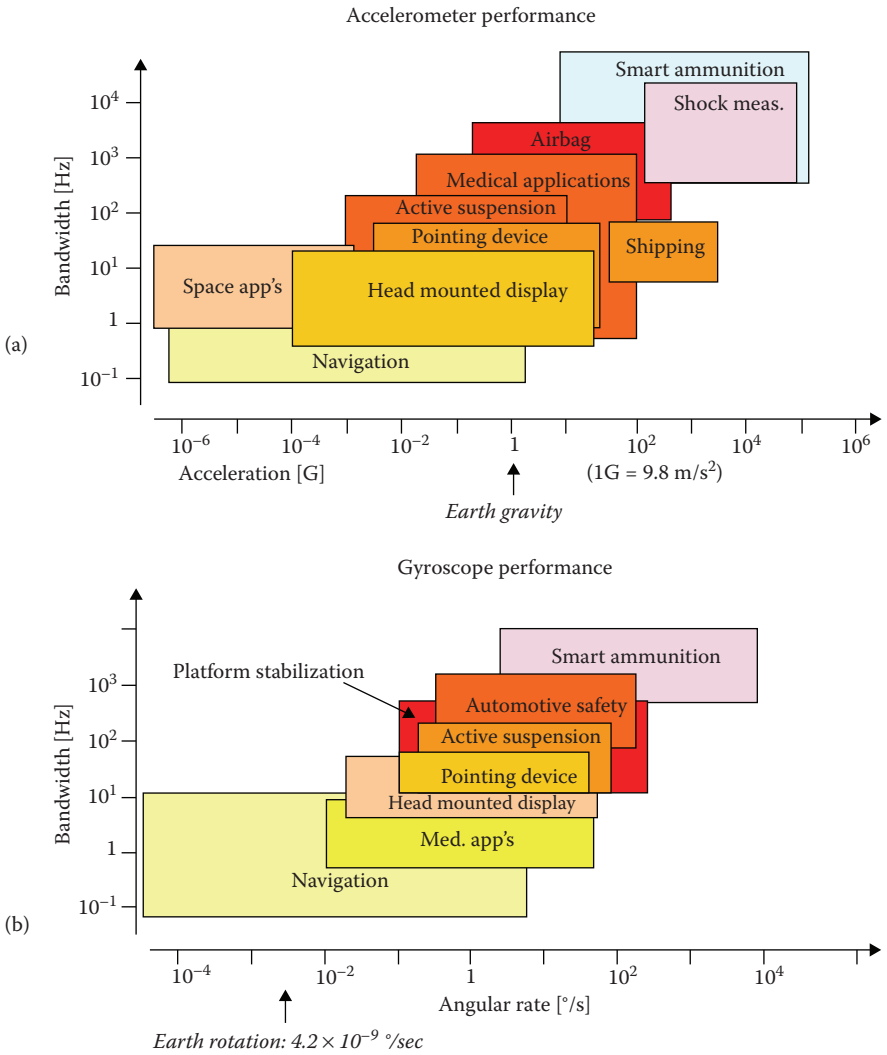

FIGURE 10.32 Overview of applications and required performances for micromachined inertial sensors. (a) Accelerometers; (b) angular rate sensors.

2010. For gyroscopes today, 4-inch wafers are still the dominant technology, but the share of 6-inch wafers is expected to grow to 60% over the next five years. DRIE and SOI increasingly are being adopted in MEMS gyroscope manufacturing.

The average price of a MEMS gyro in defense applications is 4–5 times higher than in automotive applications and more that 15 times the average sales price of consumer applications. Defense and aeronautic applications include missiles guidance, general aviation instruments, platform stabilization, land navigation, and smart munitions in the future. Gyros are made today at ADI, BEI Technologies, Inc., Honeywell, Kionix Inc., Matsushita Electric Industrial Co. Ltd., Motorola Automotive, Murata, Robert Bosch GmbH, SensoNor ASA, Silicon Sensing Systems Ltd, STMicroelectronics, and TRONIC'S Microsystems SA.

MEMS Angular Rate Sensors

Being very small, MEMS gyros obviously cannot operate on the flywheel principle, as that scales with the mass of the flywheel. Even the best MEMS motors still quickly slow down and stop if not externally actuated. The inertial mass of the small MEMS wheels is very, very small (mass moment of inertia, $I = \int r^2 dm$; with a fifth order expression like this, it becomes insignificant very fast when r is made very small). Furthermore, MEMS rotors cannot (thus far) be made so that they precess freely in three dimensions. Instead, MEMS often take advantage of the Coriolis force to detect angular rotation. The Coriolis force, named after Gaspard G. de Coriolis (1792–1843), a French mathematician, is an inertial force that must be applied to maintain a moving body's

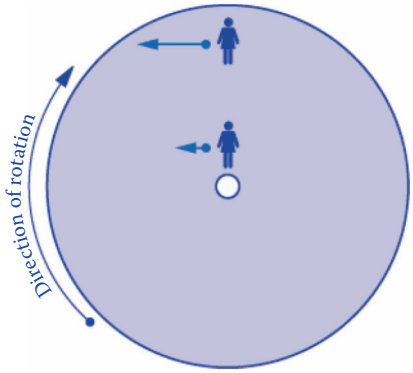

FIGURE 10.33 Illustration of the Coriolis force. A person moving northward toward the outer edge of a rotating platform must increase the westward speed component (blue arrows) to maintain a northbound course. The acceleration required is the Coriolis acceleration. (From 2003. *Analogue Dialogue* 433–37.) New iMEMS angular-rate-sensing gyroscope [John Geen (john.geen@analog.com) and David Krakauer (david.krakauer@analog.com), Analog Devices, Micromachined Products Division.]

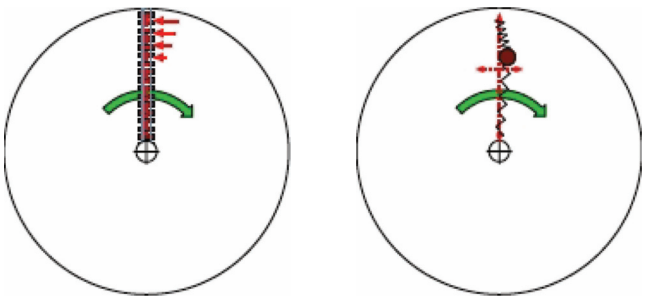

FIGURE 10.34 How to use the Coriolis force in a micro-electromechanical system device.

course on a rotating surface. Motion in a rotating reference frame leads to "sideways" movement. Coriolis showed that if the ordinary Newtonian laws of motion of bodies are to be used in a rotating frame of reference, an inertial force, acting to the right of the direction of body motion for counter-clockwise rotation of the reference frame or to the left for clockwise rotation, must be included in the motion equations (see also Figure 10.33 and Volume I, Chapter 6, "Centrifugal Fluidic Platform—CD Fluidics").

If the path of the moving body on the rotating surface is constrained, the constraining device will feel the Coriolis force (Figure 10.34). By measuring the imparted force (or its effect on an oscillator), we can measure the angular velocity. Almost all MEMS rate sensors use this feature.

The double-ended tuning fork (DETF), shown in Figure 10.35, is one of several structures that is used as the basis of a MEMS rate sensor based on the Coriolis force. One pair of tines of the DETF is driven into primary flexural vibration by a drive-oscillator, thus providing the moving body for the Coriolis force to work upon, as shown in Figure 10.35. The tines of the fork are made to vibrate in opposite directions but in the plane of the fork, which represents the primary flexural vibration mode. The Coriolis force tends to displace the tips of the fork out of this plane, forcing the tips to describe an ellipitical path as the rotation excites a secondary mode of resonance, a torsional mode coupling with the first flexural mode. A quartz DETF from Systron Donner (Concord, CA; http://systron.com) exploits the piezoelectric properties of

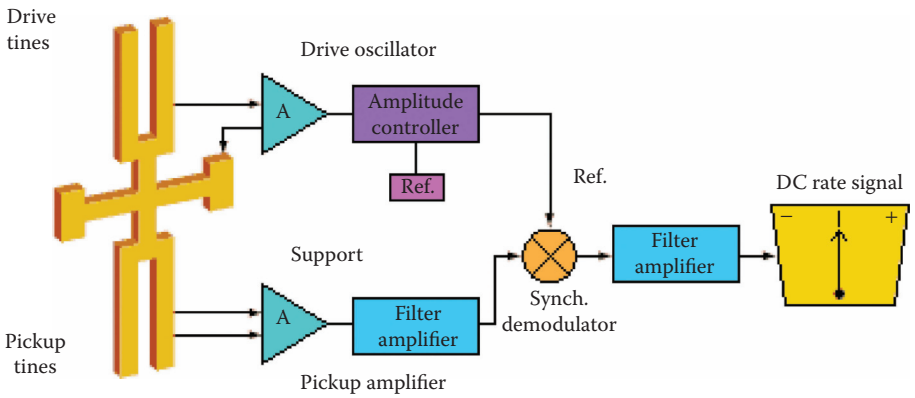

FIGURE 10.35 DETF for a rate sensor. The DETF structure may be etched from quartz or dry etched in the epilayer of a silicon-on-insulator wafer and released by wet etching the oxide layer underneath (from an older version of the http://www.systron.com website).[24]

the material to both excite and sense flexural and torsional vibration modes. The same company made a Si DETF; in this case, the DETF is dry etched out of the episilicon layer of an SOI wafer and under-etched by wet etching. To drive a Si DETF, electrostatic drive electrodes need to be implemented; otherwise, the device works just like the quartz DETF device. Although it gives up some accuracy, the Si device is considerably less expensive and has more than enough accuracy for many applications.

Daimler Benz AG, Stuttgart, Germany, uses a single tuning fork based on SOI micromachining technology for angular rate sensing. The tines of the silicon tuning fork vibrate out of the plane of the die, driven by a thin-film piezoelectric aluminum nitride actuator on top of one of the tines. The Coriolis forces on the tines produce a torque moment about the stem of the tuning fork, giving rise to shear stresses that can be sensed with diffused piezoresistive elements. The shear stress is maximal on the center-line of the stem: this forms the optimal location for the piezoresistive sense elements. The selling price of angular rate gyros such as Bosch's surface-micromachined gyro and Systron Donner's or Matshushita's tuning forks was approximately $25 in 1996, and they were relegated to the top of the line model vehicles.

Other types of angular rate Si sensors, taking advantage of the Coriolis effect, are under development based on comb or ring structures, and both surface and bulk-micromachined sensors have been demonstrated. A comb has the advantage of a larger capacitive area; however, the ring has the advantage of better vibration immunity.

One common comb design, as illustrated in Figure 10.36a, for ADI's ADXRS angular rate sensors, is a proof mass, which can move along the two in-plane

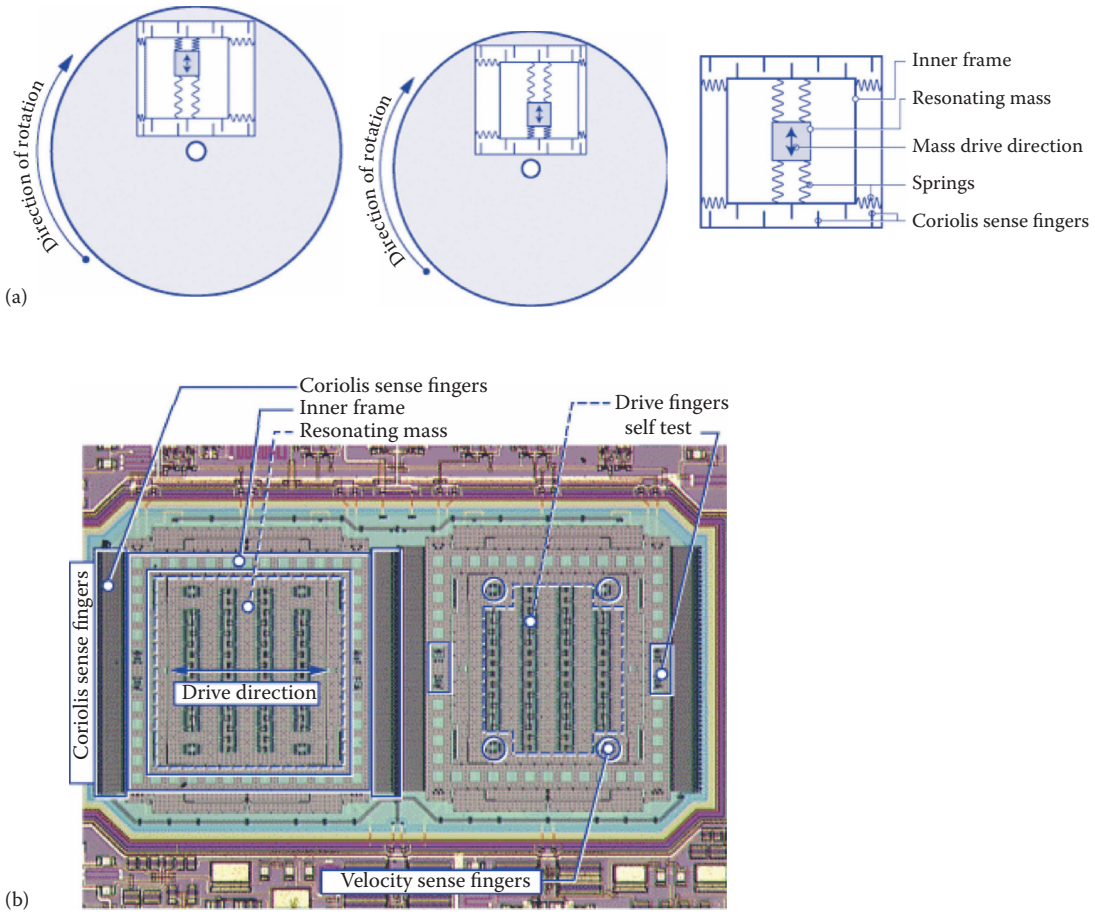

FIGURE 10.36 (a) Design principle behind the ADXRS150 and ADXRS300 from Analog Devices. These yaw-axis gyros have full-scale ranges of 150 and 300°/s, but they can measure rotation about other axes by appropriate mounting orientation. (b) The ADXRS sensors include two structures to enable differential sensing in order to reject environmental shock and vibration. (From 2003. *Analogue Dialogue* 433–37.) FIGURE 10.37 Operating principle of the rotating ring gyroscope.

axes through a suspension system. The suspended mass is surface-micromachined from polysilicon and tethered to a polysilicon frame so that it can freely resonate only along one of the two in-plane axes. To measure the Coriolis acceleration, the frame containing the resonating mass is in turn tethered to the substrate by springs situated at 90° relative to the resonating motion. With the resonating mass moving, and the surface on which the sensor is mounted rotating, the mass and its frame experience the Coriolis force. ADI's ADXRS sensors measure the displacement of the resonating mass and its frame due to the Coriolis effect through capacitive sensing elements attached to the resonating mass. The comb design in this sensing approach refers to the Coriolis sense fingers that are used to capacitively sense displacement of the frame in response to the force exerted by the mass. These sensing elements are silicon beams interdigitated with two sets of stationary silicon beams attached to the substrate, just as we saw for accelerometers in Figure 10.29b.

The ADXRS gyro electronics can resolve capacitance changes as small as 12×10^{-21} farads (12 zeptofarads) from beam deflections as small as 0.00016 Å (16 femtometers). The only way this can be done in a practical device is by situating the electronics, including amplifiers and filters, on the same die as the mechanical structure. These subatomic displacements are somewhat difficult to comprehend, as the individual atoms on the surface of the moving parts are moving randomly by much more. There are about 10^{12} atoms on the surfaces of the capacitors, so the statistical averaging of their individual motions reduces the uncertainty by a factor of 10^6. So one might wonder whether we can do better by removing the air molecules to prevent their impacting on the sensor. The answer is no. The suspension mass weighs only 4 μg, its flexures are only 1.7 μm wide, and this assembly is suspended over the silicon substrate. It is air that cushions the structure, preventing it from being destroyed by violent shocks and crashes into the substrate. The ADXRS sensors include two identical suspended masses to enable differential sensing in order to reject environmental shock and vibration (see Figure 10.36b).

Delphi[25] and Silicon Sensing Systems (formerly British Aerospace Systems and Equipment), in collaboration with Sumitomo Precision Products Company, are using the vibrating ring gyroscope (VRG) approach to exploit the Coriolis effect.[26] In the vibrating ring approach, a ring is flexured back and forth in resonant mode. The Coriolis effect induces a flexure that is sideways (and out of phase) with the driving flexure (Figure 10.37).

This principle is further detailed in Figure 10.38, which shows a wheel that is driven to vibrate about its axis of symmetry. Rotation about either in-plane axis results in the wheel's tilting, which can be detected with capacitive electrodes under the wheel, as shown in Figure 10.38a. The Delphi-Delco CMOS integrated single-chip surface-micromachined angular rate sensor is shown in Figure 10.38b. The micromachined ring shown here is driven into resonance in the plane of the chip and its vibration forms nodal points. During angular motion, the amplitude of vibration at the defined nodal points increases, and this vibration signal is fed back to reduce the amplitude, thereby maintaining a stationary pattern with nodes at the defined locations. Sacrificial micromachining fabrication techniques are used to allow the ring and

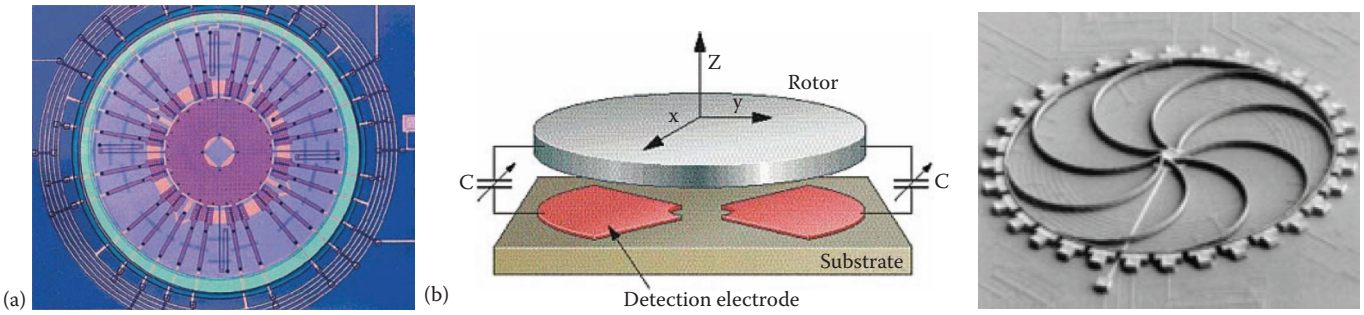

FIGURE 10.38 (a) Operation principle of the vibrating ring gyroscope. This polysilicon surface-micromachined vibrating wheel gyroscope was designed at the Berkeley Sensors and Actuators Center. (b) Delphi-Delco complementary metal-oxide-silicon integrated single-chip surface-micromachined angular rate sensor.

springs to vibrate over the surface of the IC. A scanning electron photomicrograph of the earliest version of the sensor element is shown in Figure 10.38b. The micromachined ring sensor incorporates an electroformed vibrating ring structure fabricated on a silicon IC control chip. Sensors are vacuum-sealed at the chip level using wafer-to-wafer bonding. A vacuum is required since the ring sensor has to be driven into resonance for normal operation with a quality factor >1000. Semicircular springs support the 1-mm-diameter ring and store the vibrational energy. The springs are attached to the substrate with a symmetric post. The post/spring design greatly reduces the effect of packaging stresses on the sensor.

Package-induced stress has been a longstanding problem for many other sensor programs. The Delphi-Delco angular rate sensor is a CMOS integrated single chip and is used for automotive steering assistance, active brake control, and rollover detection.

At the University of California, Irvine, Dr. Shkel's group is developing a new class of micromachined vibratory angular rate sensors, emphasizing structural design concepts to improve robustness, temperature range, and shock survivability. These sensors combine comb and ring mechanical elements. The Shkel group has explored multiple degree-of-freedom (DOF) dynamical systems in order to obtain sensing structures that are inherently insensitive to fluctuations in operation conditions, such as temperature variations, or shock loads.

The Shkel angular rate sensor, shown in Figure 10.39, features a distributed mass architecture utilizing multiple linear oscillators in the drive mode and a single central torsional oscillator in the sense

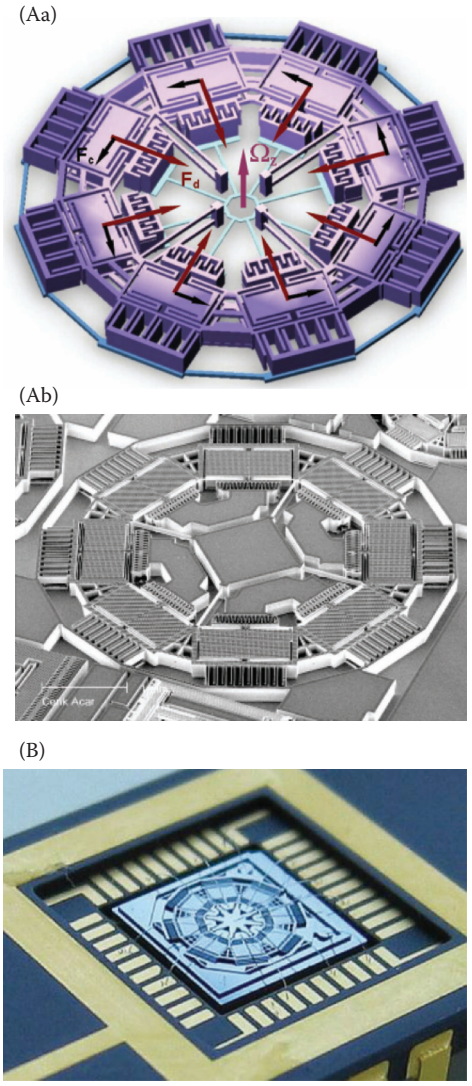

FIGURE 10.39 Microelectromechanical system angular rate sensors developed at University of California, Irvine. (Courtesy of Dr. Andrei Shkel.[27]) (Aa) Illustration of the distributed-mass gyroscope. (Ab) Scanning electron micrograph of a in-house fabricated bulk-micromachined prototype. (B) A prototype is packaged in forty-pin dual in-line package.

mode. This design address a major technical difficulty in the design of MEMS vibratory angular rate sensors, i.e., to keep matched frequencies in the drive and sense directions and eliminate structural cross-axes coupling between the drive and sense modes of the sensor.[27]

The distributed drive-mode oscillators are driven in-phase toward the geometric center of the structure and are constrained in the tangential direction with respect to the supporting frame. In the presence of an angular rotation rate about the *z*-axis, the Coriolis forces are induced on each proof mass orthogonal to each drive-mode oscillation direction. Thus, each of the induced Coriolis force vectors lies in the tangential direction, and they combine to generate a resultant torque on the supporting frame. The net Coriolis torque excites the supporting frame into torsional oscillations about the *z*-axis, which are detected by sensing capacitors.

The multidirectional and axisymmetric nature of the drive-mode oscillators has several benefits over a conventional angular rate sensor design. Firstly, since the drive forces applied to the drive-mode oscillators cancel out in all directions due to the radial symmetry, the net driving force on the structure reduces to zero and eliminates quadrature error in the presence of structural imperfections. Secondly, instability and drift due to mechanical coupling between the drive and sense modes are minimized, since the structure allows complete decoupling of multidirectional linear drive mode and the rotational sense mode. The symmetry of the drive-mode oscillator structure about several axes also cancels the effects of directional residual stresses. The most prominent advantage of the design concept is the capability to provide a wide-bandwidth operation region in the drive-mode frequency response. By designing each drive-mode oscillator to have incrementally spaced resonance frequencies, a constant total Coriolis torque is achieved over a wide range of driving frequency. If the sense-mode resonance frequency is designed to match the center frequency of the drive-frequency range, robustness and reduced sensitivity to structural and thermal parameter fluctuations are achieved. Consequently, the presented design concept results in improved robustness and stability over the operating time of the device, and it is expected to simplify the control architecture and relax tight fabrication and packaging constraints.

Conclusions

The automotive sector has long been a growth market for MEMS sensors with applications in airbag release, vehicle dynamics control, ABSs, antitheft systems, active suspension control, electronic stability programs (ESPs), tire pressure monitoring sytems (TPMSs), headlight leveling, etc. However, the industry continues to change and face new opportunities and challenges—regulations, saturation in some applications, and price erosion issues, to name a few. Today's high-end vehicles feature up to 100 different sensors. About thirty of these are now MEMS based. The market is made up of accelerometers, gyroscopes, and inclinometers, as well as pressure and flow sensors. Emerging applications include infrared (IR) sensors for air quality, microscanners for displays, and, further out, MEMS oscillators and energy scavengers for TPMS.

Consumer electronics applications are growing very rapidly and likely will overtake automotive MEMS applications. There is a convergence of requirements between the automotive and consumer electronics sensors. The automotive market can potentially derive great benefit from the advances in consumer electronics MEMS markets, but automotive accelerometer performance requirements are vastly more stringent than those of consumer electronics.

Although the electronics content of vehicles continually increases, the vehicle market itself is expanding more slowly than in previous years. The net effect is a steady increase in the value of the automotive electronics market. The use of IC-compatible process lines for MEMS production is growing. There are clearly high benefits in using CMOS or BiCMOS-compatible manufacturing lines to target high-volume MEMS markets. Some specific reasons to select monolithic integration as a solution are its cost advantages, commercial imperatives, performance advantages, and pragmatism. Nevertheless, hybrid solutions are still sometimes preferred, as they offer distinct advantages (more flexible manufacturing strategy, shorter development time, a simpler and more easily available manufacturing process, etc.). The integrated MEMS market share is expected to

grow in the future. However, there are still bottlenecks to be overcome (process standardization, MEMS is not always a large volume market, etc.).

MEMS in Medical and Biotechnology Markets: Bio-MEMS

Introduction

The per capita annual expenditure for health care is about $3000 in the United States, $3200 in Germany, and $2000 on average in Europe. The total world health market in 2004 was about $793 billion, and large segments include $280 billion for medical instruments and $484 billion for pharmaceuticals. In vitro diagnostics, surprisingly, represented only 3% of the total world health market (i.e., $27.6 billion) (see Figure 10.40; Adams Business Associates).

The biotechnology market covers a large area and has vast and crucial branches among them. Some of these biotechnology branches are genetically modified food (GMO), antibody technologies, antisense technology, biomaterials, biopharmaceuticals, drug discovery, DNA arrays, environmental/industrial biotechnology, enzymes, gene therapy, genetic engineering, genomics, informatics, instrumentation and equipment, molecular biology, pharmaceuticals, proteomics, tissue engineering, and wound care. The biotechnology market had strong growth in recent years, generating a total revenue of $126.3 billion in 2005. It represented a compound annual growth rate (CAGR) of 12.8% for the period 2001–2005. Currently, the United States dominates the market and accounts for 54.3% of the global market revenue.

Medical and biotechnology markets show strong promise for MEMS solutions in a wide variety of applications, as illustrated in Table 10.8. The medical/biotechnology application field of MEMS is referred to as bio-MEMS. In bio-MEMS, one deals with life-saving disposable diagnostic sensors, DNA arrays systems speeding up drug discovery, smart pills improving drug delivery, μ-TAS and LOC, etc., and most of those devices come with disposables. Therefore, the sales volume in bio-MEMS is expected to be eventually significantly larger than that for mechanical MEMS, where sensors are typically in use anywhere from three to ten years.

Progress in the medical and biotechnology area today is only to a minor extent derived from silicon-based bio-MEMS. It has become clear that the straight application of Si technology is very often inadequate in this field compared with its successful application in the automotive world or in mechanical and optical applications in general. Whereas in the automotive application the market for Si micromachined products is mature enough to warrant projection of realistic future revenue numbers, predicted revenues for micromachined sensors and instrumentation for biomedical and biotechnology applications mostly refer to speculation as commercial successes still remain short of realization. In the bio-MEMS field, to succeed as well as mechanical and MOEMS did, one will need to develop mass manufacturing techniques based on very large batches or roll-to-roll manufacturing on paper or plastic substrates. Through a merging of traditional micromanufacturing methods (e.g., electroplating and micromolding) with less traditional methods (e.g., lithography) and continuous manufacturing methods (R2R), we expect more bio-MEMS market breakthroughs.

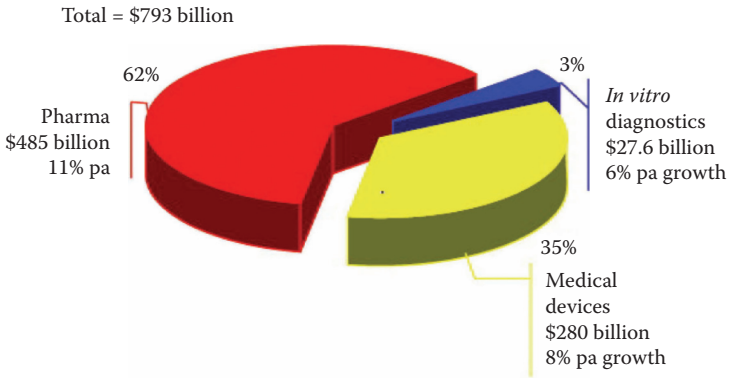

FIGURE 10.40 Global health care market in 2004. (From Adams Business Associates, aba@a-b-a.co.uk.)

Table 10.8 Medical/Biotechnology MEMS Applications

Drug Delivery Systems	Typical MEMS Example	Cardiology	Typical MEMS Example
Patches	Cygnus GlucoWatch Biographer (Figure 1.13 this volume)	Pacemakers	One- or two-axis accelerometers for activity monitoring

Neurology	MEMS neural stimulator probes		

After a write-up on the market character in this diverse field, we look at bio-MEMS applications in in vitro and in vivo diagnostics while highlighting bio-MEMS in biomedical microinstrumentation [micrototal analysis system (μ-TAS) or lab-on-a-chip (LOC)]. Micromachining efforts for building micro-instrumentation are seen today as a better approach to solving chemistry and biology problems compared with building more selective chemical sensors. Some underlying reasons are that the resulting instrument may justify significantly higher costs than disposable chemical sensors and help solve the shortcomings of chemical/biological sensors by enabling calibration, separating of bound and unbound species, cleaning the detectors, filtering out unwanted compounds, and obviating the need for very selective chemical sensors.

We conclude with a summary on progress in μ-TAS and LOC in sample preparation for molecular diagnostics, as it is felt that this is the area with the biggest need for bio-MEMS innovation.

Market Character

In terms of the business climate and funding sources in bio-MEMS, the playing ground is uneven and depends very much on the specific medical or biotechnology niche addressed. One overall trend is a move away from the initial application of μ-TAS and LOC to high-throughput screening (HTS) to its current application to point of care (POC) diagnostics instead. Even in the technology boom years (before 2001), it used to be difficult to raise money for in vitro diagnostic bio-MEMS work; for novel in vitro glucose sensors it was especially difficult, and for in vivo diagnostic devices it was harder yet. This was not only because the diagnostics industry is very entrenched and conservative but also because investors had already invested large amounts in that area with little return and because of the uncertainty of health care reimbursement. Moreover, disposable diagnostics were not necessarily perceived positively because of the waste disposal issues. Finally, one had

to demonstrate a new diagnostic sensor/instrument 80% toward a finished product in order to even be able to start talking to skeptical investors or conservative large diagnostic companies.

In the case of drug discovery, investors were, up to 2001–2002, more willing to take major risks at an early stage of the technology development. Significantly, from Figure 10.40, medical devices and pharma are a much larger market than in vitro diagnostics. Consequently most microfluidic start-up companies working on μ-TAS or LOC concepts were targeting drug discovery rather than the diagnostic area for early market penetration with bio-MEMS products. The 2001 downturn in the U.S. securities market greatly reduced the value of all of these companies, who must now make money the traditional way—by making products that someone wants to buy.

Today, the situation is reversed with diagnostic applications more attractive than research tools for biotechnology. Diagnostic products are indeed more and more appreciated as important tools in reducing costs of health care. In the past, diagnostic tests were merely used as support data for the real diagnosis, often to confirm the physical diagnosis of the doctor or for legal protection that the correct procedures had been carried out. A major change over the last 5–7 years has been the increased use in true diagnosis and differentiation of conditions in order to achieve the best treatment, i.e., theranostics bringing together the diagnostic and pharmaceutical industries. The driving force for this shift in role for diagnostic tests is the large costs for health care throughout the world at a time when the economies are less robust. The attraction of investing in the development of diagnostic products is being boosted by this change in importance and the recognition that the overall risks are reduced together with an earlier return on modest investments (Adams Business Associates, aba@a-b-a.co.uk).

With this improved business climate, improvements in bio-MEMS fluidics technologies may find now a more sizable market in better diagnostic systems, such as two-point sensor calibration schemes, sensor cleaning devices, sample preparation strategies (see further below), etc., than in HTS, where microfluidics are often only a minuscule part of a large robotic system. Diagnostics is a mass market; HTS is at most a research market (see above in the section Preamble on the MEMS market). We believe that after more significant progress is made in microfluidic platforms, there will be a resurgence of interest in chemical and biological sensors and methods to manufacture them inexpensively for diagnostic applications.

Perhaps this will produce more i-STAT (from Abbott) type products. Abbott's i-STAT, with its planar electrochemical sensor array for in vitro blood electrolyte and blood gas analysis (see below, Figure 10.42), is one of the few survivors of the many companies in the area of miniaturized diagnostics that were started in the 1980s.

The two most promising bio-MEMS areas in the short term are both in molecular diagnostics, and they involve sample preparation for DNA or RNA extraction from a wide range of samples with the same instrument (see Sample Preparation section, below) and the integration of DNA arrays with microfluidics to speed up the hybridization reaction.

In Vitro Diagnostics*

Introduction

Biomedical sensors and instrumentation for in vitro diagnostics represent a huge opportunity for micromachining in the broad sense of the word, through traditional and nontraditional miniaturization methods, continuous manufacturing methods and combinations thereof. To date, the majority of routine clinical tests are performed in large independent clinical laboratories with advanced, automated, analytical equipment. As the amount of resources spent on health care continues to soar, there is an increasing pressure for the decentralization of the POC and toward easy-to-use, miniaturized, inexpensive diagnostic machines and devices. It is in this shift that miniaturization science has so much to offer. With microinstrumentation (μ-TAS, LOC), one envisions that analyses will be performed significantly faster, without the need of

* The diagnostics market (also called *in vitro diagnostics*) includes the instruments and reagents used for the screening, diagnosis, monitoring, or prognosis of disease by laboratory techniques. The products are used in hospitals and private laboratories, in physician offices, and at other point-of-care sites (emergency rooms, intensive care units, outpatient clinics, nursing homes), as well as in home testing (primarily diabetic glucose tests and pregnancy tests).

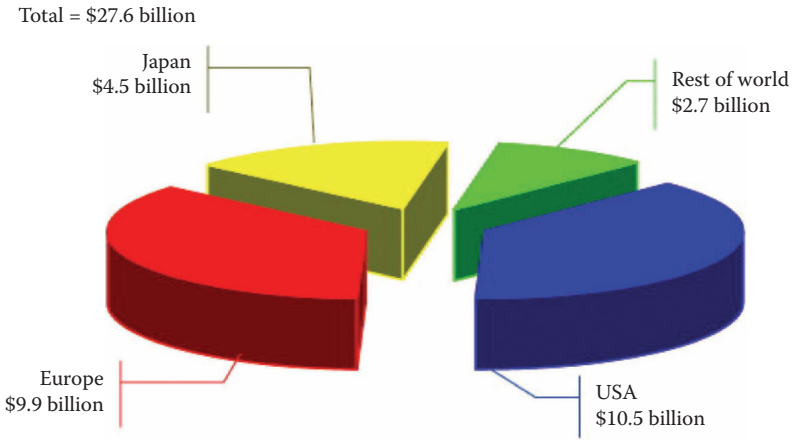

FIGURE 10.41 In-vitro diagnostic markets in 2004. (From Adams Business Associates, aba@a-b-a.co.uk.)

highly trained technicians (e.g., in remote villages, small health stations, etc.), only minute samples will be required, and dead volume in connections will be eliminated. Current in vitro diagnostic tests are categorized as clinical chemistry, blood gas/electrolytes, hematology/flow cytometry, coagulation, DNA tests (molecular diagnostics), microbiology, diabetes, urinalysis, histology/cytology. As shown in Figure 10.41, the worldwide in vitro diagnostics market was about $27.6 billion in sales in 2004, and the annual growth rate was 6% (see also Figure 10.40, which shows that in vitro diagnostics was only 3% of the global health care market for 2004).

The main areas of above-average growth (>6%) in in vitro diagnostics, identified in the 2003 report from the European Diagnostic Manufacturers Association (EDMA; see http://www.edma-ivd.be), are shown in Table 10.9.

As examples of MEMS contributions to in vitro diagnostics, we detail electrochemical sensors for blood electrolyte and blood gas analysis, glucose sensors and DNA arrays. We also cover MEMS contributions to the fabrication of miniaturized well plates, flow cytometry, and surface plasmon resonance (SPR) sensors.

TABLE 10.9 In Vitro Diagnostics with Above-Average Growth (European Diagnostic Manufacturers Association, http://www.edma-ivd.be)

Glucose tests	>10%
Cardiac tests	>20%
Nucleic acid-based tests	>20%
Genetic testing	>>20%, but from a small base

Other in vitro diagnostic applications are reviewed throughout the book. For example, contributions to the future of immunosensing were reviewed in Volume I, Chapter 7. DNA and protein arrays are also covered in Volume II, Chapter 8 (their fabrication and typical use), and the Nanogen electronic DNA array is covered in Example 8.2 of that chapter. Generic challenges concerning miniaturization in biomedical equipment, such as correct partitioning issues, were addressed in Chapter One of this volume.

Electrochemical Sensors for Blood Electrolytes and Blood Gases

Background: MEMS in Tabletop and Handheld In Vitro Diagnostics

During the past 25 years, the commercialization of MEMS for in vitro diagnostics failed to keep pace with earlier projections. We believe that an overemphasis on integration of chemical sensors with electronic functions on Si hampered the development. We suggest speeding up the progress by applying micromachining tools more correctly. This includes nonsilicon manufacturing, hybrid manufacturing, and roll-to-roll manufacturing, as covered in Chapter 1, this volume.

Progress in sensors for tabletop diagnostic instruments based on nonsilicon manufacturing techniques has been significant. The fully automated Kodak Ektachem is a tabletop clinical blood analyzer based on planar electrochemical sensor slides, and it has been on the market for some time. The Ektachem, the Seralyzer from the Ames Division of Miles Laboratory, the Refletron Plus system from

Roche Diagnostics/Boehringer Mannheim (with a sixteen-test menu), the Analyst from E. I. du Pont de Nemours, the Nucleus from Nova Biomedical, and other, similar instruments all cover a wide range of blood chemistries.[28,29] However, none of these products involve Si micromachining bio-MEMS technology. The progress enabling their development mainly was based on the development of solid-state stabilized reagents for so-called *dry electrochemistry*,[30] on miniaturized electrochemical sensors, and to a minor extent on advances in thin-film technology. Despite the many earlier claims, contributions from micromachining (Si-based or not) are mostly at the component rather than the system level, and many machining technologies are in the experimental stage. Systematic analysis of different machining options as advocated in this book (see Chapter 1, this volume) is only now starting to be applied. In the case of diagnostics, this leaves little room for Si-based technology. As a result of these analyses, one comes to the conclusion that bio-MEMS clearly counts as a fragmented set of supporting technologies rather than a monolithic new industry.

It was anticipated that Si micromachining would play a more prominent role in the development of sensors for the smaller, next-generation, handheld, and portable diagnostic instruments. In reality, micromachining and Si sensor content in the more advanced, handheld and portable, biomedical products is also surprisingly limited. Some such products for analysis of blood electrolytes and gases on the market include the GEM-Premier from Mallinckrodt Sensor Systems, the similar STATPal from PPG, and the Portable Clinical Analyzer from Abbott (the i-STAT system), providing data on sodium, chloride, potassium, urea nitrogen, glucose, and hematocrit in less than 2 min. Another handheld instrument of interest is the AccuMeter cholesterol test from Chemtrak, designed to screen lipids to evaluate cardiovascular disease risk, and the portable blood analysis systems by Diametrics Medical Inc. (electrochemical) and AVL (optical fluorescence). Abaxis introduced the Piccolo™ for general blood chemistry analysis, a small tabletop centrifugal instrument with a spinning reagent disk and optical read-out. Biologix Inc. developed the electrochemistry-based handheld pHacs STAT for blood pH, potassium, and oxygen.[28,31] Of all these products, only the i-STAT sensors are Si based. The Si avenue toward tabletop and handheld instruments has been pursued for more than thirty years with little success to report. Innovation in biomedical sensors for in vitro diagnostics has come mainly from the invention of new chemical detection schemes rather than from clever new micromachining methods. Actually, in biomedical sensors, a reversal toward hybrid and continuous manufacturing methods took place rather than a move toward more integration in Si embodiments.

Blood Electrolyte and Blood Gas Sensors

For blood electrolyte (pH, Na^+, K^+, Ca^{2+}, etc.) and blood gas (O_2 and CO_2) analysis with tabletop or handheld instrumentation, one wants to develop inexpensive, multiuse, or disposable chemical sensors. The principal approach so far has been via electrochemical technology. Microfabrication of electrochemical sensors, using IC technology, has been extremely challenging, mainly due to process incompatibility issues, packaging problems, failure to incorporate a true reference electrode, and the difficulties involving patterning relatively thick organic layers such as ion-selective membranes and hydrogels (see also Volume I, Chapter 7). Most researchers have come to the conclusion that for chemical sensing, especially for in vitro applications, a modular, hybrid approach rather than an integrated Si approach marks the road to progress. Of all the handheld biomedical analyzers on the market, only the i-STAT Portable Clinical Analyzer (Abbott, see http://www.abbottpointofcare.com/) involves Si in the sensor construction itself, primarily because of a historical production mode. Single-crystal Si, it was thought at that time, was the way to manufacture biosensors, and after the equipment investments were made, it was hard to reconsider. In Figure 10.42, we highlight the i-STAT instrument, together with a disposable sensor cartridge.

The Portable Clinical Analyzer from Abbott uses Si in the disposable chemical sensor cartridge only as a substrate and a contacting base; electronics are kept in the handheld reader, clearly a more economical approach than putting the electronics on the disposable (Figure 10.42). The sensor electrodes, gels, and membranes are all deposited with semiconductor-

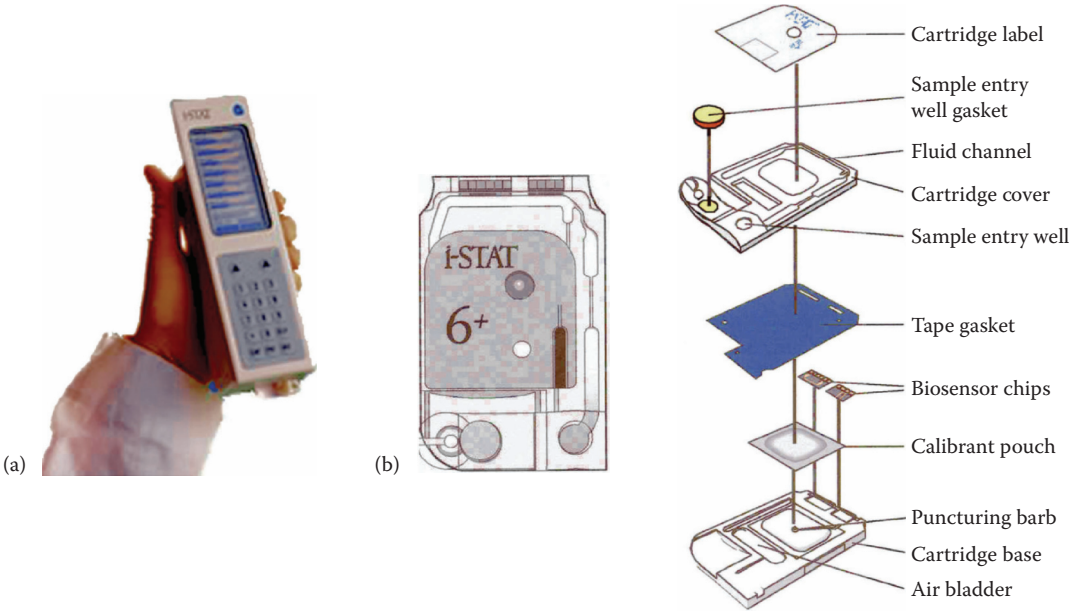

FIGURE 10.42 (a) The i-STAT portable clinical analyzer (now Abbott, see http://www.abbottpointofcare.com/) is used in conjunction with disposable cartridges for determination of a variety of parameters in whole blood. The analyzer stores up to fifty patient records and permits on-screen viewing of test results, as well as transmission of records to a data management system using infrared signals. (b) An i-STAT disposable cartridge.

type processes.[32] Without electronics onboard, the continued use of Si as a support has mostly a historical explanation. It should also be noted that the fluidic channels in the disposable i-STAT cartridge are made from molded plastic and not with Si micromachining. Abbott's manufacturing methods of the Si sensor chip in the i-STAT, after twenty years, still make it difficult to be profitable. This may be related to the manufacturing approach being silicon based and the design being integrated rather than modular. An alternative approach for the manufacture of a microfabricated, modular chemical sensor arrays is introduced in Chapter 1, Example 1.1. Epocal in Toronto uses a very different approach to making biosensor arrays compared to the methods used in manufacturing the i-STAT sensors (http://www.epocal.com). Epocal sensors are fashioned on flex circuits in a single continuous in-line manufacturing process. Flex circuits are adapted from industry standard smart card modules fashioned on 35 mm tape-on-reel format. The Epocal approach is very much the type of progress in biosensor manufacture we promote in Example 1.1.

While the number of new tools available for microfabrication, as gleaned from Chapter 1 of this volume, has grown dramatically, few methods have been gainfully applied to biosensor construction for clinical applications (some of these few methods have been reviewed in Volume II, Chapter 8). In contrast to mechanical sensors, where the excellent mechanical properties of single crystalline Si often tend to favor Si technology, the choice of the optimum manufacturing technology for chemical sensors is far less evident. For chemical sensors, the Si in the sensor often serves no other role than as a passive substrate. Consequently, the following trend emerges: whereas mechanical sensors (pressure, acceleration, temperature, etc.) are moving toward more integration embodied in CMOS-compatible surface micromachining, chemical sensors and biosensors are moving away from integration on Si and toward hybrid technology on plastic or ceramic substrates with silk-screening or drop delivery systems for the application of the organic layers.

Glucose Sensors

In vitro glucose sensing represents the single largest biosensor market, and a significant amount of all research and development in biosensors is geared toward improving this technology. Glucose self-testing by diabetics is one of the fastest growing segments of the world diagnostic market (see Table 10.9).

Diabetes mellitus is a chronic metabolic disorder that is caused by a failure of the body to produce insulin and/or an inability of the body to respond adequately to insulin. Type 1 diabetes occurs most often in children or young adults and accounts for 5–10% of the diagnosed diabetes patient population. Type 2 diabetes, or adult-onset diabetes, accounts for 90–95% of diagnosed diabetes cases worldwide, typically developing in middle-aged adults. Diabetes effects approximately 170 million people worldwide and is increasing, with the World Health Organization (WHO) predicting 300 million diabetics by 2025. The United States alone has 20.8 million people suffering from diabetes. This equates to approximately 6% of the population. Diabetes is the sixth leading cause of death in the United States (based on number of death certificates; National Institute of Diabetes and Digestive and Kidney Diseases). The global diabetes market was worth $18.6 billion in 2005, which was an 11.5% increase from 2004 sales of $16.6 billion. The United States has the dominant share in the global diabetes market, with 49.6% of 2005 global sales. The large U.S. market share is mainly due to the large population and the high prevalence of diabetes, the increasing incidence of diabetes associated with Western diets and an aging population. Kelly Close of Close Concerns Inc. in San Francisco, a consultancy devoted to diabetes and obesity research, estimates that on the basis of industry estimates worldwide sales of blood glucose meters were almost $5.9 billion in 2004. Roche Diagnostics leads, with sales of about $2.3 billion. LifeScan/J&J is second, with $1.7 billion. Together they control two-thirds of the blood glucose marketplace. Bayer, with $800 million, and Abbott Diabetes Care, with $790 million, are neck and neck for third place. The worldwide market for blood glucose test strips and monitors is currently almost $3 billion, and the market is growing rapidly at a sustained rate of 13% a year (for some example blood glucose monitors see Chapter 1, this volume, Figure 1.7). The most prominent method currently available for collecting blood glucose remains the painful and messy finger prick procedure. The recommended sampling rate is four times a day, further discouraging compliance. The need for a painless testing glucose sensor (minimally invasive) is a challenge that many MEMS engineers have worked on. A new method that permits painless blood testing while providing results that meet current standards of accuracy and reliability is key to success (for two examples of blood/interstitial fluid collections devices, see Figure 1.15a with a lancet for blood collections device, and Figure 1.15b for interstitial fluid collection using a laser puncture).

Three generations of glucose sensor technologies are reviewed in Volume I, Chapter 7. A breakthrough came with the 1987 introduction of the amperometric glucose sensor by Medisense (now owned by Abbott), which proved that small, planar electrochemical probes can compete with colorimetric paper strips. The Medisense/Abbott glucose sensor, the Precision QID (shown in Volume I, Figure 7.80), is based on an innovative mediator chemistry and a traditional thick-film manufacturing process. The sales of mediated amperometric biosensors now represents a dominant 65% of the world biosensor market.[33] A comparison of manufacturing techniques for these types of sensors reveals the difficulty of competing using a Si-based approach. One often forgets that in biosensors such as glucose sensors, one is not competing with an expensive serial manufacturing process but with continuous, printing-type processes (see Chapter 1, this volume), making products even cheaper than in a Si type batch production. The cost target for a disposable glucose sensor is about $0.10, about a factor of 10 less than an unpackaged physical sensor die. Unless a significant performance advantage arises, Si technology cannot compete. It is our belief that, besides new chemistries, continuous processes to manufacture disposable electrochemical sensors will be the ultimate answer to the pressing need for disposable, inexpensive diagnostics (see Chapter 1, Figure 1.17, where we used the manufacture of a disposable glucose sensor to illustrate our streamlined decision-making process). A way to go about continuous biosensor manufacture is demonstrated in Chapter 1, Example 1.1: "Proposed Scenario for Continuous Manufacture of Polymer/Metal-Based Biosensors." Besides Abbott's ExacTech blood glucose monitoring system, there are similar products by Johnson & Johnson (Lifescan) and Wampole Laboratories (Answer).[28]

The future of the glucose sensing business is quite intertwined with new sampling methods. Research is emphasizing minimally invasive, noninvasive, and continuous monitoring of blood glucose levels. MEMS microneedles are under development for minimally invasive sampling by several research groups in academia. One example of a minimally invasive method, recently taken off the market, is the GlucoWatch biographer from Cygnus (see Chapter 1, this volume, Figure 1.13). In this device, glucose is extracted through the skin by electro-osmosis, and the glucose is measured amperometrically.[34] Kumetrix (http://www.kumetrix.com) replaces the typical lancet and blood-testing strip with a battery-powered, handheld diagnostic instrument using disposable MEMS cartridges, consisting of a microneedle with a cross-section of about 100 µm, a silicon cuvette (a chamber for the blood sample), and a small window. The device uses capillary action to painlessly draw approximately 100 nL of blood into the cuvette, where it is mixed with a chemical reagent. A laser then measures the glucose and the blood's glucose level is displayed. The MiniMed continuous glucose monitoring system (CGMS; MiniMed Inc., Sylmar, Calif.) is the first commercially available continuous glucose monitor. Each sterile, disposable sensor (again an electrochemical type) used with the CGMS can provide a continuous glucose profile for up to 72 hours. Glucose concentration is measured in the interstitial fluid every 10 seconds, and an average glucose value is stored in memory every 5 minutes. A communications device enables data stored in the monitor to be downloaded and reviewed on a personal computer. A performance evaluation of this very promising technology is reviewed by Gross et al.[35]

The glucose sensor field became relatively stale after the introduction of the MediSense technology. A promising new research direction is touched upon in the section on in vivo diagnostics below and involves glucose binding protein for the detection. Roe and Smoller wrote a very comprehensive review on the state of the art of bloodless glucose measurements as of 1998,[36] and a review of noninvasive glucose monitoring was presented by Klonoff in 1997.[37] Heller and Feldman recently reviewed in vitro electrochemical sensors.[38]

The next generation of electrochemical sensors will be planar, thick-film, hybrid devices, which will have the cost and fabrication advantages of solid state technology but will likely still have some of the same limitations as present electrochemical sensors, that is, repeated calibrations to compensate for long-term drift and the need for periodic maintenance. An important lesson in reviewing this micromachining application is that there is as much need for further optimization of deposition of chemical sensitive layers as for exploration of new manufacturing options. Investigating continuous printing processes for electrochemical sensor manufacture will be most rewarding in the future (see Chapter 1, this volume, Example 1.1). In the meantime, a modular approach with thick-film deposition processes is advisable. Some of the calibration and cleaning problems will be resolved by implementing more sophisticated plastic molded microfluidics.

DNA Arrays

Molecular diagnostics is another one of the fast growing in vitro diagnostic applications (see Table 10.9). With microarrays or DNA chips, thousands of genes or representative oligonucleotide fragments can be arrayed on a single microchip and hybridization with complimentary strands can be sensitively detected (see Volume II, Figures 8.16 and 8.17). The fabrication methods and uses of DNA arrays are reviewed in Volume II, Chapter 8. The two most significant applications for DNA chips are believed to be in gene expression profiling and single-nucleotide polymorphisms (SNPs). In expression profiling, the chip is used to examine the amounts of messenger RNA, which controls how different genes are turned on or off to produce certain types of proteins and cells. If the gene is expressed in one way, it may result in a normal muscle cell, and if expressed in another way it may result is a tumor (see Volume II, Figure 8.23). By profiling the minute variations in a person's DNA called *single-nucleotide polymorphisms* (SNPs) and correlating these to a person's ability to metabolize a drug, personalized drug therapy might become a reality.

When biotechnology started flirting with DNA arrays and microfluidics-based companies, the MEMS market character changed overnight. The opening

salvo was perhaps given on March 2, 1995, when Glaxo Wellcome (now GlaxoSmithKline) acquired Affymax, a DNA array company, including its ownership interest in Affymetrix, for $650 million, before there was even a product on the market. This was uncommon for the "traditional" MEMS companies who had always needed to show product revenue and even then got rewarded with only modest initial public offerings (IPOs). Microfluidic companies that were early players in the DNA market fray include Aclara Biosciences, Affymetrix, Nanogen, Caliper, Cepheid, and Orchid. There is some overlap between microfluidics companies and DNA array companies, and there will be much more in the future. The author expects great merit in merging DNA arrays with microfluidics, as it will enable sample preparation for diagnostic DNA arrays and enable working from cruder samples for high-throughput screening or gene expression. All the listed companies did go public and enjoyed large capitalizations due to the explosive stock market and generous evaluations associated with biotechnology companies in general. The "technology bubble" of 2001 took down much of these gains, but it is expected that these array companies will recuperate. The wide acceptance in the United States of genetic testing is not about "if" but about "when," and it will be a burgeoning bio-MEMS application. It is not clear today, though, what is the right format to present molecular diagnostic panels to the market; should it be in small panels and handheld readers for the point-of-care (POC) market with a variety of individual cartridges/test panels (say a chip to screen for population linked genetic diseases, a separate heart disease predeposition chip, etc.), or should it be a high-throughput robotized clinical diagnostics laboratory with hundreds of test panels?

Until large market molecular diagnostic tests, preferably with an instrument including sample preparation, become available, the importance of DNA microarrays in research for disease diagnosis, understanding drug interactions and determining drug candidates is expected to keep the DNA array market growing more slowly. Molecular diagnostics today is less dominated by giant multinationals than traditional diagnostics, and tests are performed in many different specialty labs and are still quite expensive (from a few hundred dollars to several thousands of dollars), so there seems to be a more positive outlook for potential new players.

In 2005, revenue for the total U.S. DNA microarray market totaled approximately $446.8 million, and it is expected to rise to $532.1 million by the end of 2012 (Frost & Sullivan). The compound annual growth rate (CAGR) for 2005 to 2012 is estimated at 10.9%.

Protein chips are also expected to emerge, driven by advances in proteomics. Yet despite their apparent similarity to DNA arrays, protein arrays represent a much smaller market, precisely because they are as finicky as the protein elements spotted/patterned on their surfaces. The biological activity of the capture protein elements, whether antibodies or proteins, must be maintained. One has to be able to print them while preserving their activity, and for a commercial product, the arrays have to be stable for years. As a result, there are relatively few protein arrays on the market. Those that are available come in two basic flavors: general protein arrays and antibody arrays. Protein arrays from Invitrogen, ProtoArray microarrays, are finding utility in various applications, including discovery of autoantibody biomarkers, identification of novel kinase and ubiquitin ligase substrates, and elucidation of protein interactions. Antibody arrays serve a different purpose. Available from such suppliers as Clontech, Thermo Scientific, and Sigma-Aldrich, these products enable protein profiling, examining how levels of several hundred proteins change in response to some treatment. Thermo Scientific's LabVision antibody microarray includes 720 antibodies, and Clontech's Ab Microarray includes 512. Typically, protein samples are labeled with Cy3 and Cy5 dye, and this allows the arrays to be visualized using most standard DNA array scanners.

Miniaturized Well Plates

Almost any new fluidic platform faces the daunting challenge of how to either incorporate or displace the current standard method of dealing with small amounts of chemicals, i.e., the use of miniaturized well plates and associated liquid dispensing systems, as shown in Figure 10.43.

Economic and technological forces are driving the continued push toward further miniaturization

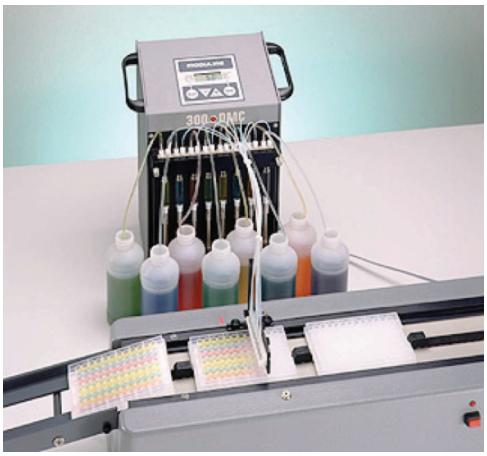

FIGURE 10.43 The 300 DMC dispenser configured for filling 96-well plates using eight different reagents (http://www.varivest.com).

of assays in plate wells for high-throughput screening (HTS) or high-volume diagnostics (Figure 10.2). In HTS, the number of potentially useful molecules is increasing, and the time during which the discovered molecules have a proprietary, strategic advantage is decreasing—in other words, the evaluation of more samples in a shorter amount of time with finite resources compels miniaturization. The number of samples has increased dramatically, primarily because of the concurrent advent of combinatorial and automated synthesis methods together with more precise biochemical or genetic definition of targets using genomic approaches. A first step in the miniaturization process for HTS and high-throughput diagnostics was from test tubes (1-mL range) to 96-well microplates (0.1-mL range) and, more recently, to 384-well (10-µL range) and 1536-well plates (1-µL range). With a 1536-well plate, ultra-high throughput (arbitrarily defined as 10^5 samples per day) becomes feasible. There are some reasons not to miniaturize and push to 1536-well plates and beyond. Certain assays become impossible if wells are too small. Cell-based assays, for example, cannot be miniaturized below 100–1000 cells without cell-to-cell variability becoming the dominant source of sample-to-sample variation, and cells are hard to accommodate in microfluidic systems. There is also substantial capital investment required for laboratories that are not already outfitted with pipetters and automated systems capable of reliably addressing 1536-well plates. For reading, 1536-well compatible readers tend to be more expensive than those limited to 384 wells, and the speed advantage of 1536 is difficult to obtain without expensive charge-coupled device (CCD camera) detectors. Some assays will suffer degradation in signal-to-noise ratio upon miniaturization (e.g., those that employ colorimetry), but many of the assays being developed have sufficient dynamic range to support a smaller format.[39] Engineering challenges associated with handling microliter volumes include: 1) evaporation, which limits the time of exposure to ambient humidity air and can cause sample-to-sample variability across the plate; and 2) fluid handling, which becomes increasingly difficult at smaller and smaller scales. As miniaturization proceeds still further, into the nanoliter-volume assays, evaporation becomes a much more significant issue. At a certain stage, a transition to fully enclosed systems, such as the microfluidic lab-on-a-chip (LOC) systems, becomes a necessity for evaporation and fluid metering. Xeotron developed the XeoChip, a bulk micromachined chip that contains thousands of three-dimensional nanochambers in an area smaller than a postage stamp (http://www.touchbriefings.com/pdf/855/fdd041_applied_tech.pdf). Each chamber serves as a protected reaction vessel for DNA synthesis and subsequent bioassay for use with conventional microarray scanners. The same system can be adapted for the synthesis of RNA, peptides, and other organic molecules.

Flow Cytometry

Flow cytometry is a method for high-throughput measurements of physical and chemical characteristics of cells and other microscopic biological particles. Typically, in commercial cytometers, optical measurements are made as particles are passing, single-file, through a sensing region. The particles are constrained to such a single line-up by hydrodynamic focusing. In this method, the sample flow is a narrow stream formed as the innermost flow of two concentric fluid flows (see Figure 10.44A). The faster the outer sheath flow, the narrower the inner sample flow is focused. Hydrodynamic focusing requires absolute laminar flow in all positions in the flow cell; from some high speed on, the inner stream will defocus through turbulence. Existing commercial

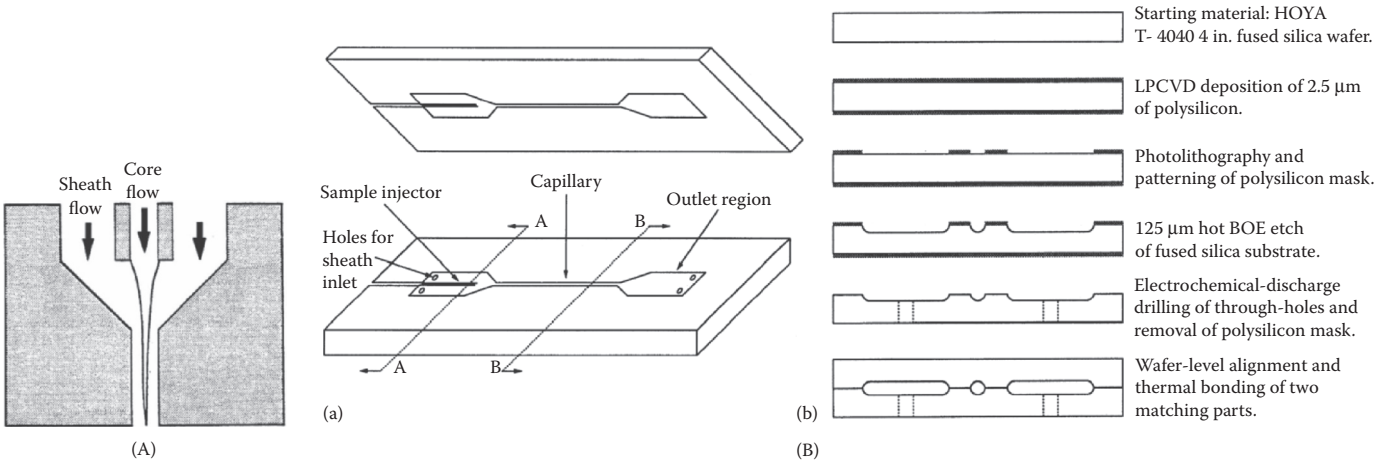

FIGURE 10.44 (A) Schematic of a flow chamber for cytometry. (B) (a) Exploded view of a fused silica flow chamber. The top and bottom have matching injection and outlet areas with a capillary joining them. Through-holes in the bottom plate are for sheath inflow and outflow. The sample is introduced through the injector into the center of the sheath flow. (b) The fabrication sequence shown along cross-section A-A. (After Sobek, D., S. D. Senturia, and M. L. Gray. 1994. In *Technical Digest: 1994 Solid State Sensor and Actuator Workshop,* 260–63. Hilton Head Island, SC.)

equipment requires frequent adjustment of the optical components, but simpler instrumentation is expected through the introduction of optical fibers replacing lenses for sample illumination and light collection. Shapiro and Hercher, in 1986,[40] suggested integration of flow channels, optical elements, and signal conditioning electronics as the next step toward more user-friendly equipment. The first such attempts led to complex micromachined sheath flow cells; for example, a five-layer stainless steel/glass laminate[41] and a four-wafer Si micromachined flow chamber.[42] Sobek et al.[43] have made a much simpler micromachined flow cytometer, which seems to put us back on the right track in terms of correct use of available micromachining tools. Cost consideration did result in a $30 \times 15 \times 1$ mm chip made from two symmetrically machined HOYA T-4040 synthetic quartz (fused silica) parts. These two parts, bonded at 1000°C, define the ovoid cross-section of the sheath flow channel, the circular cross-section of the sample injector, and the ovoid measuring capillary (Figure 10.44B). A smooth, flat surface of the capillary is essential for ensuring good optical measurements in the measuring region. The quartz starting material used here comes in 4-inch wafers, just like Si wafers. This is an important point, as most processing equipment is built to take Si wafers only. The resulting cytometer can focus a sample stream, introduced into the injector with a syringe, to a 10-μm width and can maintain this focusing to a mean velocity up to at least 10 m/s.

The next step in this development would be to find the correct package for the cytometer and an interface to the macroworld. Connectors to the sheath flow ports and the sample injection mechanisms are areas ripe for innovative approaches.

Surface Plasmon Sensor: Spreeta™

Many opportunities for innovative micromachining applications in optical immunosensors present themselves. A prime example can be found in surface plasmon sensors (SPRs). Incident plane polarized light at a specific angle can be almost totally absorbed into a thin metal film (e.g., 500 Å Ag or Au) deposited onto a prism, fiber, or waveguide surface because of resonant coupling of the light energy into a free-electron cloud within the metal (see SPR theory in Volume I, Chapter 5). This effect is known as *surface plasmon resonance* and can be extremely sensitive to the refractive index changes surrounding the metal film. By adsorption of species on the metal film, the specific angle of the light needed to create the resonant absorption changes (Figure 10.45).[44] This adsorption could be from gases or the binding of macromolecules onto the metal film. The main limitation is that the sensitivity depends on the molecular weight, or more correctly, the optical thickness of the absorbed layer, meaning that small

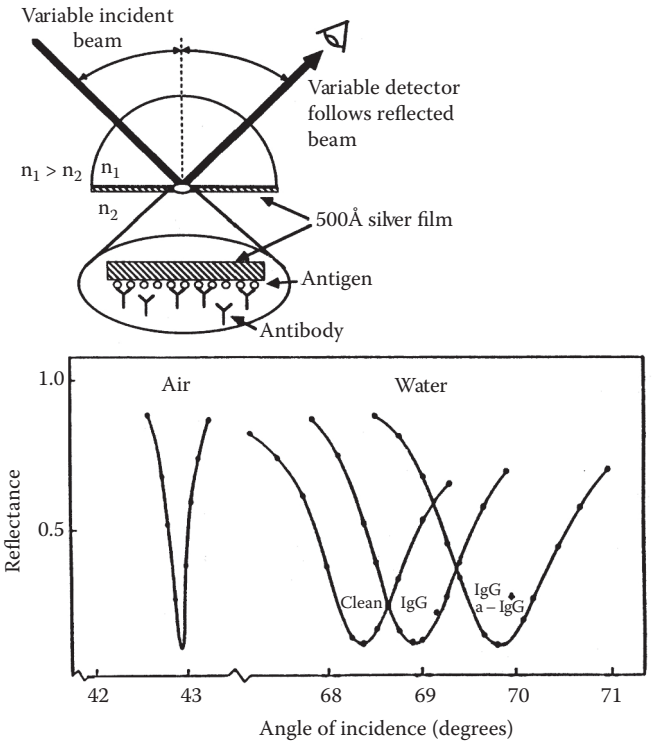

FIGURE 10.45 Measurements with a surface plasmon resonance sensor based on a prism. (From Sutherland, R. M., and C. Dahne. 1987. In *Biosensors: Fundamentals and applications,* eds. A. P. F. Turner, I. Karube, and G. S. Wilson, 655–78. Oxford, United Kingdom: Oxford University Press. With permission.)

molecules will not be good candidates. The SPR-based "immunosensor" from Amersham Pharmacia (Sweden) is a general-purpose, expensive, and rather large instrument incorporating a prism for detection and four parallel flow channels in removable sample chambers (in 2004 Amersham Biosciences, was acquired by GE Healthcare).

A significant amount of research effort is directed toward trying to miniaturize this large optical system. Comparison of diffraction gratings and prism systems clearly indicates that the diffraction grating is preferable for miniaturization. Garabedian et al.[45] attempted to micromachine the whole surface plasmon sensing system by implementing such a grating, but their resulting microinstrument is much too complex for manufacturing. An elegant alternative to both the grating and prism approaches may come from using an optical fiber or a planar optical waveguide. For example, Jorgenson and Yee[46] simplified SPR sensing dramatically by using such a fiber optic approach. As a sensing element, they used a multimode fiber with a section of the cladding removed and a thin layer of highly reflecting metal symmetrically deposited directly on the fiber core (see Figure 10.46a). This design has potential for simplified, robust, remote, and disposable sensing. Unlike traditional SPR measurements, employing a discrete excitation wavelength while modulating the angle of incidence, the SPR fiber optic sensor system uses a fixed angle of incidence and modulates the excitation wavelength. The refractive index can then be determined from the resonance spectrum in the reflected or transmitted spectral intensity distribution. In Figure 10.46b, the SPR sensing surface is enclosed in a flow-cell. Using micromachined planar waveguides in a flow-channel instead of the set-up shown here might result in a promising commercial product.

The most advanced example of a miniaturized SPR instrument is embodied in the miniature SPR sensor from Texas Instruments shown in Figure 10.47.[47–49] This sensor is also an apt illustration of "functional" packaging. As seen in the schematic in Figure 10.47a, light from a light-emitting diode (LED) is reflected from a gold surface in the LED

optical plastic substrate/package and is picked up on a photodiode array embedded in the same package. Also contained in the same package is a polarizer for the light emitting diode and a temperature sensor. A plot of reflected light intensity versus angle is read out from the linear diode array as illustrated in Figure 10.48. The current noise floor of the sensor is 7×10^{-7} refractive index units. A beta-version of a cartridge-based Spreeta handheld instrument is shown in Figure 10.47c. Pricing for the disposable today is $30, and a handheld reader might cost about $250 (one-tenth as expensive as a Biacore).

In Vivo MEMS Applications

Introduction

The many problems involving biocompatibility of in vivo devices were addressed in Chapter 5, "Biocompatibility and Surface Modification," where we learned that micromachining might actually provide a way of rendering surfaces more biocompatible by patterning them. Chemical surface modifications are also discussed. After the retrenching from in vivo devices in the 1990s, progress in materials and bio-MEMS has been so swift in the last decade that the problem of in vivo

sensing is ready for a new attack. This move back to in vivo sensing is further made easier by the progress in miniaturized telemetry and micropower systems (see Chapter 9, this volume).

In Vivo pH and Blood Gases

The cost of disposable sensors for in vivo use is not as big a concern as for in vitro disposable sensors; size is more critically important because the smaller the sensor, the smaller the intrusion on the patient. It is estimated that a catheter-based pH, CO_2, and O_2 sensor array, as shown in Volume II, Example 4.2, "An Electrochemical Sensor Array Measuring pH, CO_2, and O_2 in a Dual Lumen Catheter," may cost up to $250 and would serve a market of well over $600 million a year in the United States alone. Unfortunately, the warm, wet, saline in vivo environment perhaps puts forth the most severe environment in which Si sensors might be used. No Si-based in vivo chemical sensors are commercially available today. Biocompatibility is the single most complex issue facing in vivo sensor development, and it needs to be addressed up front in the sensor design. This is in line with our philosophy of starting a sensor design from the package. The package for an electrochemical in vivo pH, CO_2, and O_2 sensor typically is a dual lumen catheter modified to incorporate the sensor structure with the required chemically sensitive materials (see Volume II, Example 4.2). In building such a sensor, the author at first neglected to investigate biocompatibility issues up front and instead concentrated on the embedded micromachined electrochemical sensors.[50] The measurements obtained in saline solutions were encouraging, but the funding for continued research dried up before serious biocompatibility testing could be started. The development of the disposable in vivo pH, CO_2, and O_2 probe, the room-temperature micro electronic chemical smart sensor (RT-MECSS) took four years and $6 million. The RT-MECSS puts chemistry and electronics on separate planes while keeping the signal line as short as possible (see Volume II, Figure 4.99).[51] The latter represents a considerable improvement over both ISFET and EGFET (see Volume I, Chapter 7, "Ion-Sensitive Field-Effect Transistors, Extended Gate Field-Effect Transistors, and Isn't FET").

In Vivo Glucose Sensing

There have been many different technologies proposed for in vivo and ex vivo detection of glucose, and a number of ex vivo instruments and devices have been commercialized. While some of these, in particular the ex vivo ones (see above), have been very successful, a technology that meets the requirements of continuous in vivo detection of glucose and can be coupled to a miniaturized responsive delivery of insulin would be superior. Insulin delivery systems that have been developed are external and quite large in size. Ideally, miniaturized drug delivery systems would be in vivo and feature an integrated sensor for closed-loop control (see the responsive drug delivery pill in Volume II, Figure 4.100). Developing systems that are capable of both in vivo detection of biomolecules and delivering a drug is complex and requires the merging of technologies from chemistry, chemical engineering, micromachining, biomaterials engineering, and pharmaceutical science. For example, an ideal in vivo biosensor must be capable of long-term, rapid, reproducible detection of its target biomolecule at physiological levels, must be biocompatible, and must be amenable to miniaturization/microfabrication. Also, the insulin delivery system, controlled by the glucose sensor, should be capable of fast response and hold a sufficient amount of insulin to justify the long-term implantation of the device. The low success level achieved in designing in vivo miniaturized systems so far may partially stem from the fact that when developing these systems, researchers have placed more emphasis on one particular aspect than on others. Some of the persistent difficulties associated with glucose sensors include manufacturing reliability and consistency, short life spans, and cost. The number of biosensors with demonstrated capabilities for in vivo sensing is also limited.[52] Most sensors in the market today utilize glucose oxidase since the enzyme is stable and the cost is low. However, major disadvantages with using glucose oxidase are that a number of in vivo endogenous species are electroactive at the applied potential required for peroxide formation[52] and the production of H_2O_2 renders the eventual disintegration of these sensors.

As we saw in Volume I, Chapter 7, binding proteins associate with a particular analyte in a highly specific manner. Daunert et al. utilized this property in the development of reagentless optical biosensors.[53–56] Specifically, one of the many proteins of interest is the glucose and galactose binding protein (GBP). Glucose binding induces a hinge motion in GBP, and the resulting protein conformational change constitutes the basis of the sensor development. Labeling this protein with a fluorescent probe allows for the monitoring of this change without the addition of any external reagents or substrates. In order to obtain maximal signal versus background fluorescence, it is important that the fluorescent probe be attached to a single site (e.g., a unique cysteine) and at a position where maximum conformational change occurs. This approach has been shown to yield sensors with improved detection limits.[56]

As mentioned above, the most undesirable effect of current daily glucose monitoring is the frequent fingerstick glucose monitoring that the patient needs to perform. Even the more successful implantable devices, such as the MiniMed Continuous Glucose Monitoring System (currently being evaluated in several clinics throughout the United States), need frequent recalibration. This is due to the direct correlation between sensor response and the time-dependent enzyme activity. The use of GBP labeled with fluorescent compounds that have a long lifetime can afford sensors with longer service lives. Lifetime measurements are dependent on the glucose concentration but independent of the concentration of the fluorescently labeled protein present.[57] Thus, since these sensors do not require an active enzyme, a reduction in calibration frequency can be achieved. It is this type of sensor we envision combining with the smart pill in Volume II, Figure 4.100 (pharmacy-on-a-chip).

μ-TAS and LOC in Sample Preparation for Molecular Diagnostics

Introduction

Micromachining and genomics parallel each other in perceived value to society and much is expected from a merging of both fields. Bio-MEMS, in principle, holds the potential to revolutionize molecular diagnostics, as it could lead to much more compact, potentially disposable, and well-integrated molecular diagnostic systems. As we saw in Volume II, Chapter 8, the use of photolithographic techniques has already permeated molecular biology; they are used, for example, to make DNA arrays (e.g., Volume II, Figure 8.16). To enhance DNA hybridization speed, DNA arrays have been embedded in all types of fluidic structures. The principal advantages associated with a bio-MEMS, μ-TAS/LOC approach include the following:

- Small instrument footprint
- Multiplexing so that several analyses can be completed simultaneously
- Microfluidics for fluid manipulation, often obviating the need for traditional macropumps
- Excellent potential for integrating various components onto the device
- Reduced volume requirements for sample and reagents (often expensive)

Here we analyze specifically bio-MEMS contributions for sample preparation in genomics. Like packaging in the semiconductor industry, sample preparation is an area that has been less vigorously pursued than developing the assay itself; perhaps it is perceived as somewhat less glamorous, as is packaging in the IC industry. But, like IC packaging, sample preparation is of overwhelming importance to the end customer. The benefit in developing miniaturized devices for sample preparation in genomics is the low dead volume requirement associated with accuracy, costs of reagents, and small overall footprint, and the difficulty is having enough copies for the analyte to be detectable. The latter implies a flow system reducing the volume during the sample preparation step.

Types of Samples

Procedures for preparing samples for chemical analysis vary dramatically from sample to sample and from analysis to analysis. To reduce the complexity of the discussion, we single out for closer scrutiny the challenges faced in preparing samples for molecular diagnostics. Specifically, we investigate the feasibility of performing sample preparation in a small-footprint integrated instrument capable of performing all the aspects of a common biological DNA assay. The preparation of biomedical samples

prior to the diagnostic procedure is often complex, laborious, and time-consuming. It varies, even within the more limited application of DNA testing, depending on the sample type, for example, urine, whole blood, plate bacterial cultures, serum, stool, tissue, etc. Today, the preparation of such samples involves several different instruments and intensive manual operations such as centrifugation, heating and cooling, mixing with reagents, filtration, etc. For most clinical diagnostics, sample preparation is actually the rate-limiting step. In the case of whole blood samples, red blood cells (RBCs) must be separated from leukocytes [white blood cell (WBC) count for 0.2% of human blood cells: 1 μL of whole blood contains 5×10^6 RBCs and 7×10^3 WBCs) and other cells (bacteria, virus particles, etc.). Red blood cells do not have nuclei, the source of nucleic acids, but they do contain contaminants, which interfere with nucleic acid amplification [polymerase chain reaction (PCR)] and other enzymatic manipulations (e.g., both proteins and metal complexes such as hemoglobin bind with nucleic acid). Isolated leukocytes and bacteria samples must be lysed before the extraction of nucleic acid can take place. A traditional procedure for blood DNA isolation comprises separation of the white cell fraction from the whole blood, lysis with detergent, and digestion of proteins with proteinase K (1–6 hours) to purify the target material from contaminating proteins, followed by extraction with phenol-chloroform and precipitation of DNA with alcohol. DNA is not soluble at high ethanol concentrations, so it precipitates out as long strands. Salts, such as sodium chloride, also greatly aid in precipitating DNA. Tissue samples primarily contain cells and connective tissue, which also must be degraded before DNA extraction. The first step in the DNA extraction procedure from tissue is typically to boil a small amount of the tissue in a 5% Chelex solution. The boiling helps to break up the cells in the preparation and denatures proteins. The Chelex protects the DNA sample from DNAases* that might remain after the boiling and that could subsequently contaminate the samples. In the diagnostic approach of the future one envisions a small footprint instrument and a test specific disposable cartridge providing a "sample to answer" solution.

* DNAases are enzymes that occur naturally in all body tissues. They cut DNA, rendering it unsuitable for PCR. Magnesium ions are essential cofactors for DNAases. Chelex resin binds with cations, including Mg^{2+}. By binding with the magnesium ions, the Chelex resin renders DNAases inoperable, thus protecting DNA from their action.

General Sample Preparation Protocols

Sample Size

Miniaturization is a mixed blessing in the case of the amount of sample required to detect a given analyte concentration. That volume is determined by the following:

$$V = \frac{1}{\eta N_A C_i} \tag{10.1}$$

where η = sensor efficiency, with a value between 1 and 0

N_A = Avogadro's number (6.02×10^{23} mol^{-1})

C_i = the concentration of analyte i (moles/L)[58]

The sample volume required is fundamentally dictated by the concentration of the analyte one wants to measure. Manz et al. examined the use of very small sample sizes and concluded that microfluidics is a desirable approach for many diagnostic applications.[59] They summed up their analysis in a graph of target analyte concentration versus required sample volume. This graph shows that many biological chemicals associated with clinical chemistry assays (between 10^{14} and 10^{20} copies/mL) and immunoassays (between 10^7 and 10^{18} copies/mL) might be readily assayed with very small sample volumes, in the range between picoliters and microliters. However, Petersen et al. pointed out that numerous chemicals (and organisms) are routinely present at much lower concentrations, from less than 100 to 10^7 copies/mL.[58] These low-concentration samples include most sources of DNA, which must be detected and analyzed in a growing number of new diagnostic tests. In Figure 10.49, Petersen et al. expand the boundaries of Manz's original graph, which spanned a concentration range from 10^8 to 10^{21} copies/mL and a volume range from 10 mL to 10^{-18} L, and clearly show that the minimum sample volume required for accurate DNA assays is a relatively large volume of 100 μL.

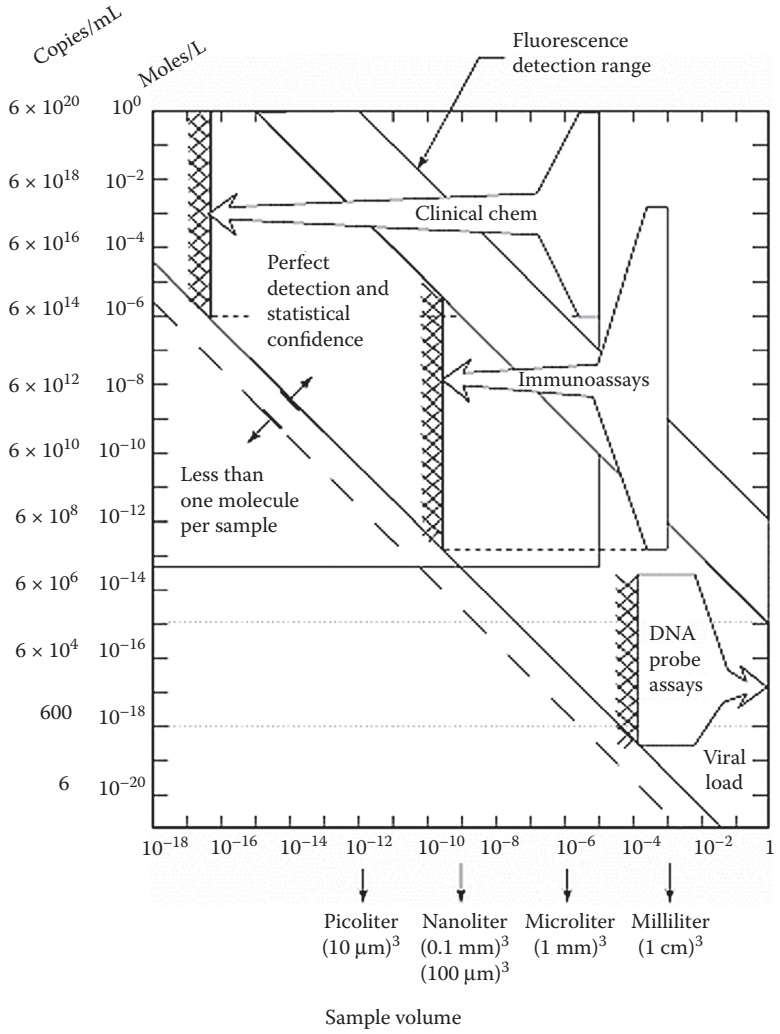

FIGURE 10.49 Sample volume. Scaling of concentrations and volumes.[58] (Courtesy of Dr. Kurt Petersen, Cepheid.)

The amount of original sample required, depending on the analysis method, and the number of DNA copies needed for detection may range from some microliters to several tens of milliliters. Figure 10.49 demonstrates that typical clinical chemistry assays (between 10^{14} and 10^{20} copies/mL) and immunoassays (between 10^{7} and 10^{18} copies/mL) are readily carried out with very small sample volumes, in the picoliters and microliters range, but numerous DNA assays deal with less than 100 to 10^{7} copies/mL[60] and may require milliliter sample volumes. To summarize, modern DNA diagnostic assays face mounting demands to detect organisms or DNA mutations at very low concentrations, often less than 100 copies per milliliter, in raw biological samples such as blood or urine. Such sensitivity requirements set fundamental physical limitations on the minimum quantities of the starting sample. Using the current nucleic acid hybridization formats and stringency control methods, it remains difficult to detect low copy number nucleic acid targets even with the most sensitive reporter groups (enzyme, fluorophores, radioisotopes) and associated detection systems (fluorometers, luminometers, photon counters, scintillation counters), necessitating a DNA amplification step, for example, using polymerase chain reaction (PCR) (see Chapter 2, "Polymerase Chain Reaction"). PCR is usually considered sensitive enough to detect as few as twenty copies of a target in any given, purified, biological sample. But if the required assay sensitivity is 100 copies per mL, then a minimum of 200 μL of the original sample must be processed to ensure statistical confidence in the result of the assay. If microfluidics and small PCR chambers are used, this means that DNA preconcentration is needed, for example, on silica-type capture surfaces

or on arrays of micromachined Si posts.[60] The latter reduces the sample size from macro to micro, which can be accommodated in a microsystem by using some type of a flow system. A modular approach, with a variety of disposable cartridges containing different fluidic options and sensor chemistries in a small fixed instrument, is the most probable solution.

Lysing

Sample preparation for DNA analysis in an integrated device includes releasing the nucleic acid from the sample by cell disruption or lysis, removing contaminants (purification), and recovering/concentrating the nucleic acid. There are many mechanical and nonmechanical cell lysis or disruption methods available. The results of these may be evaluated in terms of the activity level of a cellular enzyme released to the suspending medium measuring the efficiency of the disrupting process. We briefly review both types of lysing approaches and consider their relative merit for integration in microsystems.

Mechanical Methods

Currently, in large nonintegrated tabletop equipment, intracellular products are released from microorganisms or tissue mainly by mechanical disruption of the cells. In this process, the cell envelope is physically broken, releasing all intracellular components into the surrounding medium. There are several types of equipment for mechanical cell disruption commercially available. In a high-pressure homogenizer, a pump forces slurry of sample through a restricted orifice valve. High pressure (up to 1500 bar) is followed by an instant expansion through a special exiting nozzle. Cell disruption is accomplished by three different mechanisms in this system: impingement on the valve, high liquid shear in the orifice, and sudden pressure drop upon discharge, finally causing an explosion of the cell. This approach, although very efficient at cell disruption, is difficult to miniaturize. In a bead mill, cells are agitated in suspension with small abrasive particles. Cells break because of shear forces, grinding between beads, and collisions with beads. This approach is slightly more amenable to miniaturization. Another widely applied method is cell lysis through high-frequency ultrasound. These devices generate intense sonic pressure waves in liquid media. Under the right conditions, the pressure waves cause formation of microbubbles, which grow and collapse violently. Called *cavitation*, the implosion generates a shock wave with enough energy to break cell membranes. Modern ultrasonic processors use piezoelectric generators made of lead zirconate titanate crystals (see Chapter 8, this volume). Vibrations are transmitted down a titanium metal horn or probe tuned to make the processor unit resonate at 15–25 kHz. A relatively new development is a cordless ultrasonic processor supplied by BioSpec Products (Bartlesville, OK). With a tip diameter of 1/8 inch, it easily fits into microtubes and ninety-six-well titer plates. Ultrasonic disintegrators generate considerable heat during processing. For this reason, the sample should be kept ice-cold, and one should be aware that free radicals can be generated during sonication and that these radicals may react with biomolecules. Ultrasonic disruption is an attractive approach for miniaturization of the cell lysis process.

Mechanical disruption methods suffer several drawbacks. Because cells are broken completely, *all* intracellular materials are released. Therefore, the DNA must be separated from a complex mixture of proteins and cell wall fragments. Cell debris produced by mechanical lysis often consists of very small fragments, making the solution difficult to clarify. Moreover, complete product release often requires more than one pass through the membrane disruption device, exacerbating the problem by further reducing the size of the fragments. These fragments are difficult to remove by continuous centrifugation because the throughput of a centrifuge is inversely related to the square of the particle diameter. Filtration is complicated by the gelatinous nature of the homogenate and by its tendency to foul membranes. Because of these drawbacks, several nonmechanical cell lysis approaches have gained favor.

Nonmechanical Methods

Nonmechanical lysis includes thermal, electronic, and chemical methods. Chemical permeabilization

of cells can be achieved in numerous ways.[61,62] The most important are enzymatic lysis (e.g., with lysozyme), detergents, and osmotic shock. Chemical methods extract intracellular components from microorganisms by permeabilizing outer cell wall barriers. This can be achieved with organic solvents that act by creation of channels through the cell membrane. Some of the solvents that have been used for this purpose are toluene, ether, phenylethyl alcohol, dimethyl sulfoxide (DMSO), benzene, methanol, and chloroform.

Chemical permeabilization can also be achieved with antibiotics, thionins, surfactants (e.g., NP-40, Triton X-100, Brij, Duponal, CHAPS, SDS, etc.), chaotropic agents, and chelates. An important example in the latter category is EDTA, widely used for permeabilization of Gram-negative microorganisms. Its effectiveness is a result of its ability to bond the divalent cations Ca^{++} and Mg^{++}. These cations stabilize the structure of outer cell membranes, by bonding the lipopolysaccharides to each other. Once these cations are removed by EDTA, the lipopolysaccharides are removed, resulting in increased permeability of the outer cell walls. Chaotropic agents, such as urea and guanidine, are capable of bringing hydrophobic compounds into aqueous solutions. The relative ability of various anions to influence the structural stability of protein (and DNA) in general follows the series $F^- < SO_4^{2-} < Cl^- < Br^- < I^- < ClO_4^- < SCN^- < Cl_3CCOO^-$. This ranking is known as the *Hofmeister series* or *chaotropic series*. Fluoride, chloride, and sulfate salts are structure stabilizers, whereas the salts of other anions are structure destabilizers. Salts that stabilize proteins enhance hydration of proteins and bind weakly, whereas salts that destabilize proteins decrease protein hydration and bind strongly. In other words, the denaturing effect of chaotropic salts is related to destabilization of hydrophobic interactions in proteins. High concentrations (6–8 M) of compounds that tend to break hydrogen bonds, such as urea and guanidine salts, also cause denaturation of proteins. These substances apparently disrupt hydrogen bonds which hold the protein in its unique configuration. However, there also is evidence suggesting that urea and guanidine hydrocholoride may disrupt hydrophobic interactions by promoting the solubility of hydrophobic residues in aqueous solutions. Detergents break open (lyse) cells by destroying the fatty membrane that encloses them. This releases the cell contents, including DNA, into the solution. Detergents also help to strip away proteins that may be associated with the DNA. Enzymes can also be employed to permeabilize cells, but this method is often limited. Enzymes used for enzymatic permeabilization are glycanases, proteases, and mannase. The main drawbacks of employing enzymatic means for recovering intracellular products in large-scale processes are cost and the necessity of removing the lysing enzyme from the product. Basic proteins, such as protamine, or the cationic polysaccharide chitosan can permeabilize yeast cells. Antibiotics that affect bacterial cell-wall biosynthesis, causing loss of viability and often cell lysis (penicillins and cephalosporins, bacitracin, cycloserine, vancomycin), may also be used. Similarly, mammalian cells can be permeabilized by exposure to several natural substances such as streptolysin or even viruses.

While cells exposed to slowly varying extracellular osmotic pressure are usually able to adapt to such changes, cells exposed to rapid changes in external osmolarity can be mechanically injured. This procedure is typically conducted by first allowing the cells to equilibrate internal and external osmotic pressure in a high-sucrose medium and then rapidly diluting away the sucrose. The resulting immediate overpressure of the cytosol is assumed to damage the cell membrane.

Repeated freezing and thawing will thermally lyse a cell, and in some instances, the target DNA may be released by elevating temperatures simultaneously with the denaturing step performed in PCR.[63]

Electronic lysis of cells has been reported by Cheng et al.[64] and Lee and Tai.[65] Of the different types of nonmechanical lysing, the electronic and thermal approach is the most amenable to miniaturization. Chemical approaches should be ranked according to the amounts of chemicals required; the lesser the amount, the more suited the approach to miniaturization

Table 10.10 summarizes some lysis methods and subsequent purification and recovery steps.

Table 10.10 Cell Lysis, DNA Purification, and Recovery

Process	Technical Difficulty	Costs	Efficiency	Ease of Miniaturization
Lysis				
Mechanical	High	High	High	Of the mechanical lysis methods reviewed, ultrasonic is most amenable
Chaotropic	Medium	Medium	Medium	Depends strongly on the volume of reagents involved
Thermal	Low	Low	Low	Easy to miniaturize (sometimes this step can be combined with polymerase chain reaction)
Purification				
Ion exchange	Medium	Medium	High	Easy to implement on a miniaturized platform
Beads	Medium	Medium	Medium	Somewhat more cumbersome
Molecular weight cutoff membranes	Low	Low	Low	Easy to implement on a miniaturized platform
Recovery				
Silica elution	Low	Low	High	If a flow-through system is used, miniaturization of low-salt buffer is easy to accommodate
Bead elution	Low	Low	Medium	More cumbersome
Membrane elution	Low	Low	Low	Easiest to miniaturize

Examples of Integrated Sample Preparation

Over the last ten years, several attempts have been made to miniaturize molecular diagnostics, inclusive of sample preparation, in the areas of biological warfare agents and point of care.[58,66–74] These efforts involve microfluidic systems, in which the entire protocol from sample collection through PCR, and in several cases all the way to detection, is embedded in one integrated instrument. In Table 10.11 we review a few of these prototype DNA analysis devices (expanded from Yuen et al.[75]). Extensive efforts pertain to isolating white blood cells from whole blood through the use of micromachined filters (arrays of posts, tortuous channels, comb-shape, and weir-type)[66,76,77] and different designs of silicon microfilters (3–10 μm) across microchannels.[78,79] All these designs feature a high efficiency for separating red from white blood cells. More recently, Yuen et al.[75] CNC-machined a Plexiglas-based module integrating white blood cell separation and nucleic acid amplification reactions. This module comprises a heater-cooler for thermal cycling and a series of 254 × 254 μm microchannels for transporting human blood and reagents in and out of an 8–9-μL dual-purpose (cell separation and PCR) glass-silicon microchip. The filter in this case was of the weir type (3.5-μm filter gap). A region in the human coagulation Factor V gene (226-bp) was directly amplified by the microchip-based PCR from DNA released from white blood cells isolated from the weir filter section.

In the sample preparation approach of the company Tecan Boston (now defunct), a compact disc (CD) (the LabCD; see Volume I, Figure 6.88 and Figure 10.50 below), was used as a sample preparation stage (see also Table 10.11 below). The physics behind this centrifugal microfluidic platform is covered in Volume I, Chapter 6, and its prototyping is detailed in Chapter 5, this volume. The Tecan Boston prototype combined sample preparation and PCR, while detection was performed separately on an ethidium-bromide-stained gel electrophoresis slab. The disposable disc is shown in Figure 10.50. The sample preparation protocol employed is as follows: 1) mixing raw sample (5 μL of whole blood or *Escherichia coli* suspension) with 5 μL of 10 mM NaOH; 2) heating to 95°C for 1–2 minutes to lyse cells, releasing DNA and denaturing proteins inhibitory to PCR; 3) neutralization of lysate by mixing with 5 μL of 16 mM Tris-HCl (pH 7.5); 4) mixing of neutralized lysate with 8–10 μL of liquid PCR reagents and user-selected primers; and 5) thermal cycling. Samples of whole blood or *E. coli* were run on the discs shown in Figure 10.50 using a rotational profile that sequentially drives fluids past capillary valves *d*, through mixing channels *e*, to receiving reservoirs. Reservoirs *a*, *b*, and *c* contain sample, NaOH, and Tris-HCl, respectively. At the lowest rpm,

TABLE 10.11 Prototype Integrated DNA Analysis Devices

Sample Preparation	Biochemical Reactions	Detection	Fabrication Methods for Device	Source
RNA purification from 1 mL of serum samples spiked with different copy numbers of an RNA transcript that contained a partial HIV sequence	Reverse transcription-PCR, nested PCR, DNase fragmentation and dephosphorylation, and terminal transferase labeling	GeneChip hybridization	Conventional CNC machining	Anderson et al.[67]
White blood cells isolation from <3 μL of human whole blood	PCR using integrated heater-cooler to provide thermal cycling	Not applicable	Conventional CNC machining (standard microfabrication techniques for microchips)	Plexiglas microchip module[75]
5 μL of whole blood or *E. coli* suspension	PCR using thermoelectric devices on a spinning personal computer board platen	Detection is performed separately by electrophoresis	CNC machining of polycarbonate or poly(methylmethacrylate) disc combined with lithography in polydimethylsiloxane for smaller fluidic features	Tecan Boston[74]
Starting from the DEP collection of intact bacteria in a 70-μL sample to DNA hybridization assay (*SLT1* gene of *E. coli*),	Strand displacement amplification, dielectrophoretic collection of *E. coli* bacteria, electronic DNA hybridization	Electric field driven DNA assay	Laminated flexible substrates with electrode arrays (using integrated circuit lithography)	Nanogen[73]
Spores in paper products (0.5 gm in 10 mL of water)	PCR on material eluted from a Si DNA extraction chip (set of 200-μm-high columns, 18 μm in diameter, with a pitch of 34 μm)	Gel electrophoresis in a separate step	Acrylic or polyester plastics and Si chips	Cepheid[60]
30 green-fluorescent protein-transfected THP-1 cells in 25 μm of whole blood	Real-time-PCR	Real-time PCR	Droplets containing surface-functionalized superparamagnetic particles	Institute of Bioengineering and Nanotechnology[80]

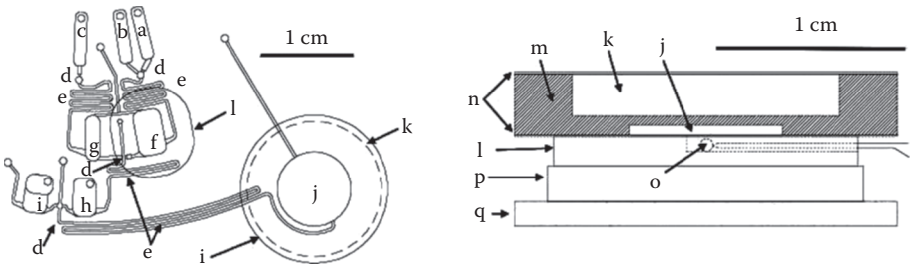

FIGURE 10.50 On the left is the polymerase chain reaction (PCR) structure. The center of the disc is above the figure. The elements are as follows: (a) sample; (b) NaOH; (c) Tris-HCl; (d) capillary valves; (e) mixing channels; (f) lysis chamber; (g) Tris-HCl holding chamber; (h) neutralized lysate holding chamber; (i) PCR reagents; (j) thermal cycling chamber; and (k) air gap. Fluids loaded in (a), (b), and (c) are driven at a first rpm into reservoirs (g) and (f), at which time (f) is heated to 95°C. The rpm is increased and the fluids are driven into (h). The rpm is increased and fluids in (h) and (i) flow into (j). On the right, the cross-section shows disc body (m), air gap (k), sealing layers (n), heat-sink (l), thermoelectric (p), personal computer board (q), and thermistor (o). (Courtesy of Dr. G. Kellogg, Tecan Boston.)

sample and NaOH mix in mixing channel *e* and move to reservoir *f* while Tris-HCl moves to holding reservoir *g*. Chamber *f* is the lysis chamber, which heats the sample/NaOH mixture up to 95°C for 1–2 minutes to lyse the cells and denature the proteins. Heating of the lysis chamber is accomplished by a thermoelectric element mounted on a personal computer-board platen *q* on the spindle of the rotary motor and connected by a slip-ring to a stationary power supply and a temperature controller. The lysis chamber sits on top of a brass heat-sink *l* mounted directly onto the thermoelectric element *p*. A thermistor, *o*, mounted in the heat-sink, enables closed-loop temperature control. By driving up the rpm, the Tris-HCl from the holding chamber *g* and the lysed material in reservoir *f* mix in the serpentine mixing channel neutralizing the lysate and then move into chamber *h*. At yet a higher speed fluids in *h* and *i* flow into the PCR chamber *j*. The PCR reagents used were either reconstituted beads or a solution of necessary reagents held in reservoir *i*. Rapid cycling with small temperature gradients in chamber *j* is achieved by confining the fluid to a thin layer, 0.5 mm thick, adjacent to another thermoelectric element. Above the fluid, an air pocket, *k*, serves as a thermal insulator. As a result, most of the heat transfer occurs via the thermoelectric. Slew rates of $\pm 2°C/s^{-1}$ have been achieved with fluid volumes of 25 µL; the temperature gradients across the liquid are less than 0.5°C (from simulation and thermocouple measurements). With slight design changes, twelve structures of the type shown in Figure 10.50 may be placed on a 12-cm plastic disc. As we remarked when reviewing fluid propulsion options in Table 1.8 of this volume, a centrifuge platform is an attractive sample preparation stage (wide dynamic range, relatively insensitive to fluid composition, etc.). There is one major issue yet to be resolved, though: unless one works with all dry reagents (and has wetting take place only upon first use of the disc) the liquids held in the sample reservoirs will evaporate and distribute over time as there is no vapor barrier to stop them from expanding within the whole available open volume in the disc. The fluid gating in the disc works only for fluids, not for vapors. Electrokinetic and acoustic fluidic platforms suffer the same problem, so a major remaining challenge for developers of diagnostic platforms based on microfluidics is to implement both fluid and vapor gating. One possible solution is shown in Chapter 1, this volume, Figure 1.12, where reagents of interest are sealed in small blister pouches in a plastic laminate and only when the liquid is needed does a mechanical roller break the liquid and vapor seal. In Figure 8.52 we suggest yet another solution involving ferrowax valves on a CD platform. An external magnet can move these ferrowax plugs to pump or valve fluid plugs on the CD platform.

Kido at RotaPrep, Inc., developed the OrbiPrep system, an integrated, centrifugal sample preparation system. This station does not involve PCR yet, so it is not listed in Table 10.11 but PCR will be integrated in the future. It combines magnetism,[81] centrifugal acceleration, dynamic reagent dispensing,[82] and the Coriolis effect[83] in a system that performs automated, simultaneous milling/homogenization of up to twelve biological samples, followed by the extraction, washing, and elution of purified DNA from each sample. The system consists of a computer-controlled centrifuge-like device that accepts either two-sample rotors or twelve-sample rotors. Figure 10.51a shows a two-sample rotor on the device with its main components labeled. The device is also able to dispense accurate volumes of up to four discrete reagents into the center ring-shaped distribution trough of the rotor while it rotates. This is accomplished by fixing four dispensing needles to the lid of the device. When the lid closes (Figure 10.51b), the tips of the needles enter the trough to rest below the top plane of the rotor. Walls within the trough divide the entering stream of liquid equally among the sample preparation units of the rotor. Figure 10.52 shows the different stages of operation of the OrbiPrep. After loading the samples with buffer into the milling chambers through the sample loading ports, the milling stage involves a slow rotation at 400 rpm that causes the free moving magnet within each milling chamber to oscillate in the radial dimension as the rotor turns through the static magnetic field. The yellow arrows depict the trajectory of the free-moving magnet. The resulting milling action homogenizes biological samples, releasing their contents. The slow rotation prevents the liquid in the milling chamber from moving to the next

chamber held there by capillary forces (i.e., the rotation rate is below the burst frequency of the capillary valve separating the two chambers, see Volume I, Equation 6.141). In the DNA binding step, the rate of rotation is increased to 8000 rpm. This causes liquid from the milling chamber to flow downstream (i.e., the rotation speed is now increased above the burst frequency of the capillary valve), through the prefilter, toward the silica membrane. Before the liquid reaches the silica membrane, it is mixed with ethanol that started to be dispensed through the first dispensing needle into the distribution trough. The black arrows depict the flows of the respective liquid streams and the mixing point immediately upstream of the silica membrane. The silica membrane extracts DNA from the combined liquid stream that passes through it down into the Coriolis effect flow switch. Since the rotor rotates clockwise, the stream enters the waste chamber. Washes 1 and 2 follow, as wash buffers 1 and 2 are dispensed from needles 2 and 3 in series. Since the liquid from the milling chamber has been drained, the liquid flow into the silica membrane comes only from the distribution trough, as the black arrows indicate. The rotation continues to be clockwise, so the stream from the silica membrane is directed into the waste chamber. The rotor reverses direction and resumes rotation at 8000 rpm before the elution buffer is dispensed from needle 4. The elution buffer enters the silica membrane and dissolves the DNA from it before flowing downstream into the Coriolis effect flow switch. The counterclockwise rotation causes the stream to flow into the small elution chamber, ready for use in downstream processes such as amplification by PCR. The whole process takes approximately 5 minutes to complete.

Pipper et al.[80] made a free droplet containing surface functionalized superparamagnetic particles into a virtual μ-TAS with a (sub)microliter volume. Aside from acting as the force mediators for actuating the droplet in a magnetic field, the superparamagnetic particles serve as a solid support for the sequential performance of biochemical processes. Depending on the task, the droplet becomes a pump, valve, mixer, extractor, or thermocycler. In an all-automated experiment, thirty green fluorescent protein (GFP)-transfected THP-1 cells are isolated from 25 μm of blood, 100-fold preconcentrated, purified, lysed, and subjected to a real-time PCR (RT-PCR) targeting the transfection vector all within 17 minutes. Fast thermocyles of 7 seconds take place on a disposable substrate under timespace conversion by rotating the droplet clockwise over different temperature zones.

Beyond the prototype stage, Cepheid, in 2001, introduced the GeneXpert for pathogen detection (http://www.cepheid.com). This instrument goes from raw biological sample to PCR and detection within 30 minutes. The detection technology is based on DNA amplification and real-time, fluorometric identification and quantitation. The real-time optical reading of the amplified product is based on four colors (for four targets) per disposable cartridge (the ICORE, which stands for intelligent, cooling/heating, optical reaction). Four ICORE can be loaded at the same time into a GeneXpert instrument. Cepheid's test, which looks for telltale genetic sequences, takes as little as 72 minutes. The GeneXpert machine costs $30,000 to $150,000, depending on how many tests it can run at once. Each individual test cartridge is priced at $42.

MEMS in Industrial Automation, Including Environmental Monitoring Markets

Introduction

According to the Nexus III report, industrial automation, including environmental monitoring, constituted 5% of a $12 billion MEMS market in 2004 and will be a 4% of a $25 billion MEMS market in 2009 (see Figure 10.16). MEMS pressure sensors, gas sensors, flow sensors, accelerometers, infrared imagers, angular rate sensors, temperature probes, etc., all have utility in modern industrial processes and automation. MEMS is also expected to play an important role in environmental applications. Primary environmental MEMS products are expected to be in the area of distributed sensor networks for detection of air and water pollution and in downscaled instruments such as microspectrometers, micro-gas chromatography systems, micro-ion mobility spectrometers, infrared detectors, and perhaps even electronic noses and tongues.

As a wide variety of non-silicon and traditional technologies are involved in the construction of novel industrial and environmental monitors it is harder to come up with accurate MEMS market data in industrial/automation and environmental control. Silicon technology has not penetrated this application as deeply as it has the automotive world. With a plethora of solutions and the unifying theme of silicon-based sensing missing, MEMS market numbers vary much more than for automotive sensing.

Research in industrial and environmental instrumentation miniaturization is especially challenging, as science requirements call for advances in performance with simultaneous large reductions in device mass, volume, and cost. Many conventional instruments operate at or near theoretical limits, and reducing the scale (volume and mass) often leads to sharp reduction of performance. This situation calls for new fundamental principles for instrumentation technology development. In other instances, we shall see, miniaturization is making for better instruments.

From the time a picture of a gas chromatograph (see Volume I, Figure 1.22) the size of a matchbox was printed on the cover of the April 1983 issue of *Scientific American*[84] (Terry and Angell built a first prototype between 1974 and 1975), there has been a continued effort to micromachine analytical instruments. Few MEMS-based microinstruments reached the market. They are still relatively large, tabletop or suitcase size, with only a few key components based on micromachining. One well know example is the Agilent MicroGC (Figure 10.8), looking significantly less integrated than the device suggested in the 1983 *Scientific American* article (the MTI gas chromatograph column itself is not micromachined; only the inlet and detector are). The wisdom of using Si micromachining for microinstrumentation is now in doubt, but looking at the miniaturization job from a precision engineering perspective, one becomes aware of the many alternative manufacturing options available.

MEMS Solid-State Gas Sensors

Most current solid-state gas sensors operate on the principle of modulating the resistance of a metal-oxide thick film by adsorption of gas molecules to its surface at high temperature (see Taguchi sensor, Volume II, Figures 9.11 to 9.13). Typical metal-oxide sensor materials include SnO_2, TiO_2, ZnO, WO_3, and Fe_2O_3. Each metal oxide is sensitive to different gases. For example, tin oxide is most effective at detecting alcohol, hydrogen, hydrogen sulfide, and carbon monoxide, and zinc oxide is useful for detecting halogenated hydrocarbons. Unfortunately, most metal oxides are adversely affected by humidity, which must be controlled at all times. In addition, variations in material properties require that each sensor be individually calibrated.

The market in 2000 for small solid-state gas sensors and sensor systems in the toxic and combustible gas arena was some $120 million in the United States alone. Broken down by product, the U.S. market for these chemical sensors comprises about $25 million for hydrogen sulfide, $20 million for total hydrocarbon monitoring, $12 million each for carbon monoxide and oxygen deficiency, and small percentages for a myriad of other gases. The use of a ceramic tube in a classical Taguchi sensor (see Volume II, Figure 9.11) maximizes the utilization of the power from the coiled Pt wire heater inside the tube, so that most of the power is used to heat the tin oxide covering the tube. The tin-oxide paste is applied on the outside of the ceramic body over thick-film resistance measuring pads by dip coating and is sintered at high temperature. The sintering stabilizes the intergranular contacts where the sensitivity of the gas sensor resides. The structure is not a design suited for mass production, as it involves excessive hand labor. The problems with the thick-film structure are mainly in the area of reproducibility: compressing and sintering a powder, the deposition of the catalyst (e.g., the size of palladium crystallites and how close they are to the intergranular contacts), and the use of binders and other ceramics (e.g., for filtering) are all very difficult to control. It is obvious from our discussion of the Taguchi sensor in Volume II, Chapter 9, that the application of IC techniques to Taguchi sensor manufacture can improve the state of the art dramatically in terms of the required power budget; a power reduction by a factor of ten is quite common. Unfortunately, as explained in Volume II, Chapter 9, no thin-film tin-oxide gas sensor can yet compete with the thick-film-based traditional Taguchi gas sensor in terms of sensitivity. If one could make a

thin-film tin-oxide with the same gas sensitivity as a thick film, then micromachining the heater elements, and thin-film deposition of the gas-sensitive material would further improve reproducibility and make for an excellent product. For long-term stability, relatively low temperature semiconductor catalyst should be used (perhaps operating at temperatures <200°C). Figaro Engineering Inc. of Japan pioneered the Taguchi sensor technology in 1962. This company is still one of the leaders today.

A major obstacle to more rapid progress with thin-film micromachined gas sensors remains that the sensitivity of thin films to gases is not yet very well understood. The currently available devices, already quite small and inexpensive, will only be replaced quickly when newer technology improves upon the existing product in terms of reproducibility, cost, sensitivity, response time, concentration range, specificity, reversibility, stability, and power consumption.

At this time, the best course for future progress in the Taguchi-type sensor is to continue to optimize sensitivity of thin-film oxide semiconductors, use planar Si devices (reproducibility and cost), and concentrate on implementing less power-consuming microheater elements. Along this line MicroChemical Systems (MiCS; http://www.microchemical.com) produces micromechanical Si thin-film tin oxide gas sensors. Details about the nature of the thin-film tin oxide are scarce (Figure 10.53).[85] For very low-cost and less demanding applications, the MiCS sensor might succeed, but for more demanding applications, planar thick-film structures on ceramic do present a better option.[86]

An interesting new research direction in the MEMS gas sensor arena might be to take advantage of the micromachined ceramic (Al_2O_3) structures, as illustrated in Chapter 5, Figure 5.9, for both heaters and catalyst support.

The MGS1100 carbon monoxide sensor from Motorola (Schaumburg, IL)[87] is not on the market anymore. The device incorporated a tin-oxide, thin-film sense resistor over a polysilicon resistive heater. The sense resistor and the heater reside over a 2-µm-thick silicon membrane to minimize heat loss through the substrate. Consequently, a mere 47 mW was sufficient to maintain the membrane at 400°C. There is a total of four electrical contacts: two connect to the tin-oxide resistor, and the other two connect to the polysilicon heater. The simplest method to measure resistance is to flow a constant current through the sense element and record the output voltage. Although the electronics were implemented correctly, as you would expect from Motorola, it seems like the fact that a gas sensor is only as good as the selective catalytic nature of its surface was forgotten in this sensor implementation.

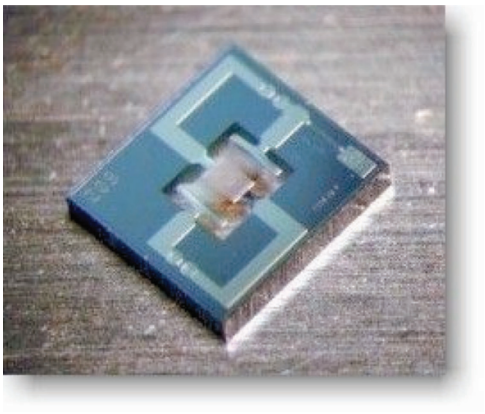

FIGURE 10.53 Microelectromechanical system gas sensor by MicroChemical Systems (MiCS; http://www.microchemical.com). Top view of the sensor chip. The key elements of the sensor are a heater that maintains the gas sensitive catalyst layer at a specific temperature (I), a thin supporting thin dielectric layer allowing very low power consumption (II), and a sensitive catalyst layer that changes resistance upon exposure to gases (III). MiCS uses proprietary technology to deposit precise amounts of nanoparticle metal oxide material on the micro hot plate. The very small grain size provides high stability and sensitivity.

The market for humidity sensing in the United States is about the same size as or larger than the total toxic gas sensor market ($120 million). A particularly interesting set of micromachined gas sensors, including humidity sensors, is based on thin-film-coated chemiresistors and acoustic devices.[88] We discussed the Jet Propulsion Laboratory (JPL) microhygrometer in Chapter 8, "SAW Example Application: Dew Point/Humidity Sensor" (Figure 8.26).

Solid State Gas Sensor Arrays: Electronic Noses and Tongues

The selectivity of a chemical sensor is the ability to measure only one chemical in the presence of many other chemicals. Because of the lack of perfect selectivity of chemical sensors, sensor arrays are often

implemented. The solid-state gas sensors described above are one of the types of sensors used in arrays in electronic noses to fingerprint complex gas mixtures (other types use conductive polymers, coated quartz microbalances, or carbon black in nonconductive polymer matrix). The sensitivity of Taguchi sensors to different gases depends principally on the choice of catalytic metals and the operating temperature. Although the selectivity of the individual sensors is limited, qualitative and quantitative gas analysis can be performed using pattern-recognition techniques. Optimally, the sensors have a wide dynamic range and a small correlation to the other sensors in the array so that each contributes as much new information as possible. When applying pattern-recognition techniques to chemical analysis one defines chemometrics. The combination of multiple gas sensors and signal analysis using pattern-recognition techniques is the concept behind the *electronic nose* or *E-nose* (Figure 10.54). The sensor array is part of a neural network sensor array (NNSA) consisting of the array, a sampling system, a flow control system, a preprocessor, and a pattern-recognition system.

An electronic nose is an example of biomimetics at work (see also Chapter 2, this volume). In animals, the olfaction system (smell) is perhaps the most mysterious of the senses: even the sense of taste, for example, consists in large part of smell. Two American scientists, Dr. Richard Axel and Dr. Linda B. Buck, who suggested an answer to the enigma of how, with only a limited number of receptors (350), people can smell more than 10,000 different odors, and recall them later, were awarded the 2004 Nobel Prize in Physiology or Medicine.[89] The initial event in the process of olfaction is the recognition of an odorant by olfactory receptors—proteins found in

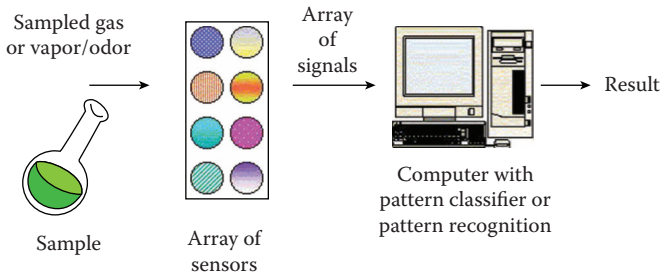

FIGURE 10.54 The electronic nose: an example of biomimetics. Electronic noses were touched upon in the context of neural network software in Chapter 9, this volume.

the olfactory epithelium. Olfactory receptors convert the "information" in odorant molecules into electrical signals that are interpreted by the brain. In animals a layer of mucus dissolves the arriving scents and separates out different odor molecules so that they arrive at the receptors at different speeds and times, so there is some type of *snot chromatography* involved as well. The brain is able to interpret this pattern to distinguish a diverse range of smells. In contrast, an artificial nose consists of a much smaller array of chemical sensors, typically between six and twelve, connected to a computer with neural net software capable of recognizing patterns of molecules. (Electronic noses are also touched upon in the context of artificial neural network software in Chapter 9, this volume.)

E-noses were popular at the end of the twentieth century and have been successfully used in a number of applications, e.g., the quality estimation of ground meat, the identification of different paper qualities, the classification of grains with respect to microbial quality, the screening of irradiated tomatoes. NASA used a JPL developed electronic nose on the space shuttle; the manufacturers of Coors beer, Evian water, and Starbucks coffee use electronic noses to test the quality of their products; and E&J Gallo Winery is trying to find out whether they can spot bad corks. E-noses also have been tested to monitor pollution, spot explosives and drugs, and diagnose diseases.

Unfortunately, electronic noses have had a hard time finding acceptance in the marketplace. A lot of training is required of both sensor arrays and the technical staff running the equipment, and the instruments are still large and expensive. The chemical sensors used in the sensor arrays drift too much, so that too-frequent calibration makes the use of the instruments cumbersome. Recognizing this problem, surviving electronic nose companies are now adding mass spectrometry to their sensor arrays (Figure 10.55).

Alpha MOS, Neotronics Scientific Lt., Illumina Inc, AromaScan Inc., and Cyrano Sciences, Inc., were all important players in this field in the 1990s. Alpha MOS, a French company, and AromaScan Inc., a British manufacturer, were the first to develop the electronic nose, or sensor array systems (SAS)

FIGURE 10.55 The Prometheus from Alpha MOS is the world's first odor and VOC analyzer that combines a highly sensitive fingerprint mass spectrometer with a large choice of patented multisensor array technologies to create an extremely flexible analysis platform (http://www.alpha-mos.com/).

technology, for commercial use. At Pittcon 2000, Cyrano showcased a portable electronic nose, the Cyranose 320, which distinguished odors using an array of thirty-two sensors. Each sensor was made of a composite of conductive carbon black and a nonconductive polymer. Today, only Alpha MOS continues as an electronic nose company. There is little left of all the other original contenders. In 2004, the Pasadena-based Cyrano Sciences was acquired by Smiths Detection for $15 million plus earn-out. Neotronics has been amalgamated into the Zellweger Analytics consortium, Illumina Inc. went on to do great things in DNA arrays (see Volume I, Chapter 7, "Bead Arrays for Detection and Analysis of DNA Sequences"), and AromScan became Osmetech, focusing on molecular diagnostics (http:// www.osmetech.com) instead.

The scientific principles of the electronic tongue are similar to the electronic nose but are applied to liquids rather than vapors. An electronic tongue incorporates electrochemical membrane-based sensors (see Volume I, Chapter 7, "Ion-Selective Electrodes") mimicking the five types of taste buds, which sense sourness, saltiness, bitterness, sweetness, and umani (deliciousness). The sensors in the array, like our taste buds, exhibit global selectivity rather than absolute selectivity; in other words, they are not selective to one chemical species, but to a wide variety. The ASTREE Electronic tongue from Alpha MOS is a liquid taste analyzer designed for taste assessment in solutions or solids dissolved in liquids. Like the human tongue, it provides a global "taste fingerprint" of a complex mixture of organic/inorganic compounds. For all tastes, it performs analysis with similar or better detection threshold than the human tongue.

Electrochemical Gas Sensors and Optochemical Gas Sensors

Solid-state semiconductor devices have been heralded as the replacement for electrochemical sensors; however, the electrochemical gas sensor sales are experiencing a growth rate of 30% per year. The latter is probably due to the slow rate of improvement in the selectivity of solid-state gas sensors and superior selectivity of electrochemical sensors brought on the market by companies such as City Technology (http://www.citytech.com) and Neotronics.[90] There is quite some consolidation going on in gas sensor companies. Neotronics and Sieger have been amalgamated into the Zellweger Analytics consortium, and more recently, First Technology has acquired City Technology and Capteur Sensors, while EEV is now part of E2V Technologies. There is plenty of opportunity in the application of MEMS to room-temperature electrochemical sensors, although these sensors are typically small already, they are not made in batches yet.

An optochemical gas sensor approach developed by Quantum Group Inc.[91] was adopted by First Alert as an inexpensive and selective fire alarm (http://www.qginc.com/products.html). This room-temperature sensor comprises a porous, semitransparent substrate (e.g., a glass frit) into which a self-regenerating chemical sensor reagent, selective for CO, is impregnated. Reaction with CO is fast, very selective and changes the color of the reagent. This color change is picked up by a diode photo-detector. Oxygen in the air regenerates and clears the substrate slowly back to its original color (~30 minutes). In this fashion, the sensor is biomimetic, simulating human response to airborne toxins such as carbon

monoxide, mercury, ethylene oxide, volatile organic materials, and hydrogen sulfide. This is a very inexpensive and promising approach, and with further fine-tuning of the chemistry of various sensor reactants, we might expect a large family of products based on this optochemical approach, with a selectivity akin to an electrochemical sensor but at a cost similar to that of a solid state gas sensor.

The biomimetic sensor has a functional lifetime of over one year, and the mimicking of the human response to toxins is achieved by the use of a molecular encapsulant that encapsulates at least one gas component. Work is concentrating on extending the sensor's lifetime and speeding up the regeneration of the sensor. The optochemical gas sensor from Quantum Group Inc. could be miniaturized by using nontraditional manufacturing techniques, but finding selective chemistries for other gases, such as NO_2, O_3, and H_2S, is a higher priority.

ISFETs

ISFET technology was covered in Volume I, Chapter 7, "Ion-Sensitive Field-Effect Transistors, Extended Gate Field-Effect Transistors, and Isn't FET." In the United States, ISFETs are manufactured only at the University of Utah, Salt Lake City. Orion Fisher, Corning, Sentron, and Rosemount, as well as UniFet, Inc. (San Diego, CA) sell ISFET-based pH sensors in the United States but do not produce them in-house. Honeywell sells the DuraFET, and in a detailed evaluation study, Sandifer and Voycheck called this sensor remarkable rugged, very stable, and accurate.[92] Orion and Rosemount buy their pH ISFETs in research quantities from Neuchatel (Switzerland) and target the food industry where glass pH electrodes cannot be used for food (pH measurement in dough, for example). Unisensor recently acquired Sentron (www.unisensor.ch). These commercially available ISFETs are for pH only and feature a simple pH sensitive inorganic membrane on the gate. To modify FETs with polymer membranes for detection of other ions is difficult because of the thickness of the membrane and the need for a stable internal reference electrolyte.

As we pointed out in Chapter 1, this volume, usually it is simpler and less expensive to build electrochemical sensors on a nonsilicon substrate (see, for example, the reference electrode in Chapter 1, this volume, Figure 1.18).

Gas Chromatography

Gas chromatography is a technique widely used for the separation and analysis of gaseous samples. A typical gas chromatograph (GC) consists of a carrier gas supply, a sample injection system, a separating fused silica column, an output detector, and a data processing unit, as depicted in the block diagram in Figure 10.56.[93] Separation of the sample vapors is achieved via their differential migration through a capillary column (see Volume I, Chapter 6). A precise and reproducible volume of sample vapor is injected at the input of the column by a valve and swept through it by an inert carrier gas. The

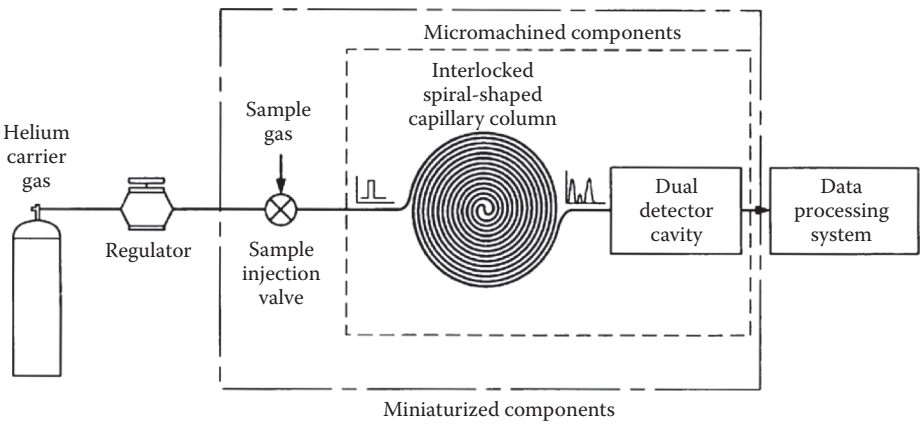

FIGURE 10.56 Functional block diagram of a gas chromatography (GC) system. (After Kolesar, E. S., and R. R. Reston. 1995. Separation and detection of toxic gases with a silicon micromachined gas chromatography system. *Proceedings of the International Conference on Integrated Micro/Nanotechnology for Space Applications, National Aeronautics and Space Administration (NASA) and The Aerospace Corporation*. Houston, TX, October 30–November 3, 1995, pp. 102–14.[93])

column is lined with a liquid stationary phase, a substance capable of absorbing and desorbing each of the component vapors depending upon their unique partition coefficients. The migration rate of each vapor along the column depends on the sample injection pressure, the carrier gas velocity, the temperature, and the degree to which the vapor is absorbed by the stationary phase. The column's output is thus a series of vapor peaks separated by regions of pure carrier gas. To detect those peaks, the output gas stream from the column is passed over a detector that measures a particular property of the gas, such as the thermal conductivity, which can be related to the concentration of sample vapor in the carrier gas. The detector produces a signal, which is amplified and used in the analysis of the sample mixture; the identity and quantity of each vapor in the mixture can be determined from, respectively, its retention time in the column and the area under its output peak.

Gas chromatography systems tend to be large, fragile, and bulky pieces of laboratory equipment, and miniaturization would present many advantages:

- Integration of the instrument into a process
- Portable and handheld units
- Fast response time (1 minute or less) in comparison with a large unit with comparable plate numbers (see Volume I, Chapter 6, "Scaling in Analytical Separation Equipment")
- Less calibration and carrier gases needed
- Low dead volume
- Higher accuracy

The first integrated GC, consisting of a long separating column, a sample injection valve, and a thermal conductivity detector (TCD), fabricated on a single Si wafer, was developed at Stanford as early as 1974 (see Volume I, Figure 1.22). The Agilent MicroGC, based on that original work, uses a traditional fused silica capillary column but retains the other micromachined components (Figure 10.8). By the time MTI produced its first GC, with a 100-µm diameter, fused silica GC columns had become commercially available, and they proved to be superior to the Si micromachined columns. The reasons behind their superiority must be sought in the perfect symmetry of the monolithic silica columns. The smoothness of the stationary phase coating the inside of a capillary column is a function of the profile symmetry. The uniformity of coating thickness is extremely important to maintain very sharp separation peaks. The micromachined designs described in the literature usually consist of a cover sheet of Pyrex glass, which is anodically bonded to a U-shaped, V-groove, or rectangular groove etched in Si.[94] Columns also have been made by joining two U-grooved halves. All these designs have a major potential deficiency: they are bound to accumulate coating on the corners or joints, leading to a less perfect separation.[95] Analytes spend a longer time in areas where the coating is thick than in places where it is thin, leading to a broadening of peaks. Thermal gradients might also be induced by joining dissimilar materials, again causing peak broadening. It also should be realized that the column has to be replaced on a regular basis because of aging and fouling. Therefore, the price of a total integrated system would have to be very low.[96]

Research efforts for making better micromachined GC columns are continuing,[93] but since existing fused silica columns are perfectly adequate, the focus would be more gainfully put on other GC problem arenas. Specifically, micromachining could be of great immediate use in the arena of better, more reproducible, miniaturized valves and fast heating and cooling of thermally isolated column and injector for fast temperature-programmed chromatograms.

A Hewlett-Packard (HP) development of a handheld GC may be the only effort that combines both excellent micromachining capabilities with a long-standing instrumentation knowledge. RVM Scientific, Inc. has also built a novel handheld miniaturized gas chromatograph for detection of contraband drugs in cargo containers and chemical weapons treaty verification. There are several small GC products now being introduced to the market. The SnapShot, for example, is a handheld GC from Photovac International Inc. (Deer Park, NY). The instrument has a battery pack providing 4–6 hours of operation and may be used for personal exposure monitoring. Besides Agilent, Stanford Research Instruments is offering rugged GCs for field use.

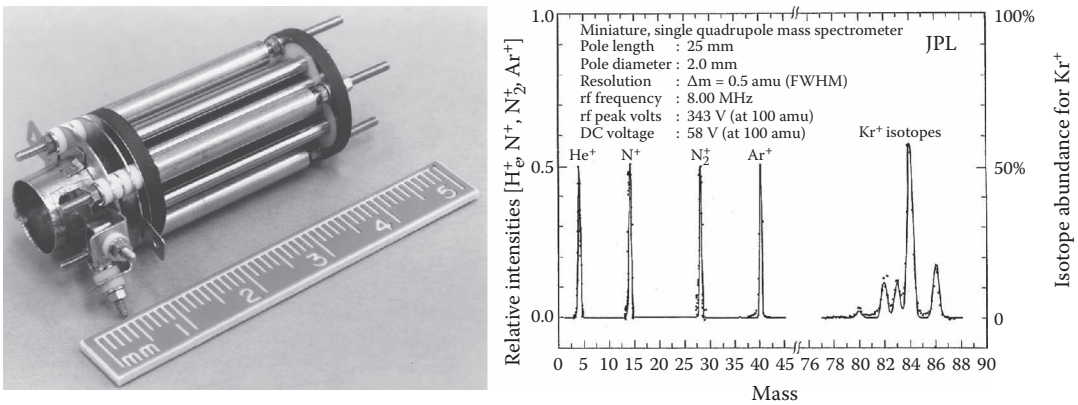
(b) A 1-cm scale array of quadrupoles for gas analysis (traditional mechanical precision machining). Built by Ferran Scientific, California.

Mass Spectrometry

Mass spectrometers (MSs) are extremely versatile tools that have found, at least for the moment, their greatest use in laboratory science. The determination of the component atomic and molecular masses and their abundance is indeed essential for the understanding of almost any chemical and/or process analysis. Lack of broader use is attributed to their large mass, volume, and power requirements. Especially powerful would be a miniaturized gas chromatography-mass spectrometry (GC-MS) combination, with the GC for the isolation of the various compounds of a complex mixture and the MS for further identification. Innovative vacuum systems, smaller GC ovens, new sample inlets, and advanced electronics are now making some of this possible. For example, a GC-MS system built in a suitcase by Lawrence Livermore National Laboratory in California for real-time field use is shown in Figure 10.57a.[97] Ferran Scientific has successfully implemented a 1-cm scale array of quadrupoles for gas analysis (Figure 10.57b), and a similar MS is under development at Jet Propulsion Laboratory (JPL) in Pasadena, California. JPL researchers suggest that the Ferran instrument lacks in mechanical precision and hence resolution. In their own work, a miniaturized quadrupole mass filter, one machined with traditional but very precise machining methods (Figure 10.58a) and one dramatically smaller in size fabricated employing LIGA (not shown), was pursued. The JPL research team deemed quadrupole and ion-trap mass spectrometers most suited for miniaturization, as their operation does not require a permanent magnetic field, and they can be fabricated as parallel arrays of spectrometers.[98] The array concept is extremely important considering the following simple scaling insights. Miniaturization of an instrument dimension, *l*, by a



(a) (b)

FIGURE 10.58 Miniature mass spectrometry. (a) Jet Propulsion Laboratory's small quadrupole array made by traditional, but very precise, machining. (b) Spectrum generated from the single quadrupole mass spectrometer in (a).

factor k leads to a cubic mass and volume reduction (l^3 scaling) and an input aperture area reduction (l^2 scaling), and thus sensitivity reduction of k^2. To offset the lost sensitivity, one can construct an array of k^2 spectrometers, all working in parallel. One ends up with a spectrometer array with a sensitivity comparable to its larger cousin but with mass and volume reductions of k. A present quadrupole or magnetic-sector instrument may be of the order of 10^4 cm^3 volume and 10–15 kg mass and may require about 20 W power for operation. The JPL traditionally machined microspectrometer, a 4 × 4 array of nine miniature quadrupole mass analyzers (Figure 10.58a), has a mass of less than 0.8 kg (including electronics), is 20 cm^3 in volume, and draws less than 8 W power. The rod alignment, straightness, and roundness accuracy for a mass range of 1 to 250 amu and a mass resolution of 0.5 amu (FWHM) at 200 amu must be 0.15% (see mass spectrum in Figure 10.58b). Initially, the rods were machined at 2 cm long, but they can be further reduced to 1.5 or even 1 cm. The alignment was carried out using a machinable ceramic alignment jig to accurately position the rods. The holes in the jigs are machined using a conventional, high-precision lathe (±0.0002-inch tolerance). With the LIGA technique, the attempt is to make the quadrupole rods 1 mm high and 80 µm in diameter, but these specifications have not yet been met. LIGA might provide more accuracy for the straightness of vertical walls, but the tolerances in the x- and y-directions are still dependent on the aligner. As we may deduce from Volume II, Figure 6.5, a 0.15% tolerance on dimensions below 100 µm is quite a challenge.

Optical Absorption Instruments

The most common analyzers used in analytical chemistry for both gases and liquids are spectroscopic absorption techniques. A considerable amount of effort has been put into miniaturization of such equipment with both traditional and nontraditional machining tools.

Consider, as an example of an environmental application, the detection of methane by means of infrared absorption (based on Beer's law, see Volume I, Equation 7.133). From Volume I, Chapter 7, we know that to obtain a better sensitivity, a longer optical path is required. To accomplish this on a small-footprint instrument of a few square centimeters, a set of LIGA-machined micromirrors may be positioned in a folded configuration, as illustrated in Figure 10.59. The infrared mirrors are preferably made from solid electroplated gold or by evaporating gold on poly(methylmethacrylate) (PMMA) walls. The vertical height of the mirrors is limited by the spot size of the infrared laser beam. The light intensity loss in the miniaturized instrument is due to absorption and scattering by the micromirrors. Gold is the preferred material for the micromirrors because of its high reflectivity in the mid-infrared region. Superpolished gold surfaces can reflect as much as 98% of an incident infrared beam in the specular direction. However, micromachined gold mirrors, electroformed or evaporated on PMMA walls, will likely have an inherent surface roughness, which may cause scattering of incident beams. Working in the infrared range presents an advantage in this case, as the roughness of the mirrors will typically be small compared with the wavelength used. With an angle of incidence close to the normal direction, one can typically accommodate up to 100 reflections before serious losses occur. With a 1.6-cm distance between mirrors, this means 1.6 m of optical path-length, which may not be adequate for a 0.1-ppb sensitivity but would serve well for applications that require only a few parts per million of sensitivity. The conclusion is that one might well be able to miniaturize a gas absorption cell, but a miniaturized infrared analyzer of this sort will be suited only to less demanding applications. No products of this

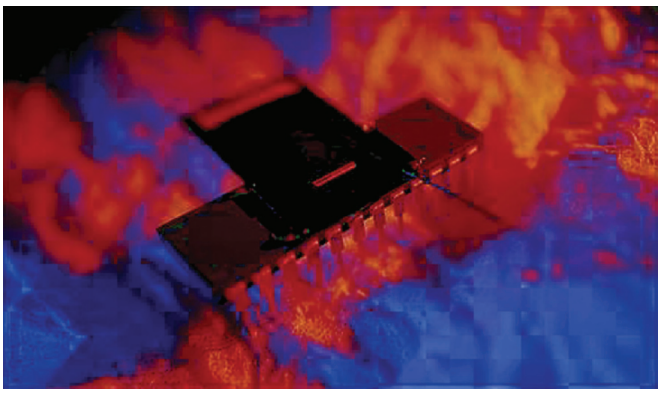
(a)



(b)

FIGURE 10.60 Microspectrometer from STEAG microParts. Schematic (a) and photograph (b).

sort are on the market yet. In Volume I, Chapter 7, "Scaling in Absorption Spectroscopy and Cavity Ring-Down Spectroscopy," we introduced the cavity ring-down spectroscopy (CRDS) technique, which represents a way around the sensitivity issue when scaling down an optical instrument. As far as we are aware, there is no MEMS version available of the CRDS.

The STEAG microParts VIS microspectrometer is a monolithic dielectric slab waveguide with integrated focusing echelette grating produced by a micromolding technique. The part sells for $100–$300. Light to be analyzed is coupled into the device by an optical fiber. Light reflected from the grating is detected by a diode array. The detector attached at the focal plane is a Hamamatsu photodiode array with 256 pixels. The STEAG microParts microspectrometer is shown in Figure 10.60.

MEMS in IT Peripherals and Telecommunications Markets

Introduction

In the past, automotive applications were setting the pace for increases in manufacturing volumes of MEMS sensors. The future will present quite a different scenario: huge growth rates in MEMS sensors are expected for applications in consumer electronics (CE) products, with a focus on IT and communications, and extensions into health care, life sciences, security systems, domestic appliances, and others. Once a MEMS device succeeds in the automotive application, with its very stringent specifications, the door is wide open to other more relaxed markets, even the consumer market. Analog Devices, for example, is now putting its surface micromachined accelerometers in video games, car and notebook alarms, smart pens, etc.

IT peripherals is a general term used to describe technologies that help produce, manipulate, store, communicate, or disseminate information. From Figure 10.16, this application area today constitutes already the largest MEMS market, dominated by hard disc drive heads, inkjet print heads and microdisplays. Interestingly, at the moment of their market introduction, the first two of these products were not even considered MEMS (see also the Preamble on the MEMS Market section, above).

To illustrate that there are many more MEMS opportunities in this market segment, consider that the mobile phone market crossed the 1 billion unit level in 2006. MEMS applications in phones include microphones/speakers (Knowles Acoustics), accelerometers (Analog Devices) for functions such as scrolling, gyroscopes (Invensense) for in-phone camera-lens stabilization, system timing products/oscillators (SiTime for myriad functions), and RF MEMS for band switching, filters (TeraVicta), and displays (Qualcom/Iridigm). The challenge for mobile phone MEMS manufacturers will be to meet the stringent price constraints demanded by the phone companies while still maintaining necessary reliability and product performance.

Read-Write Heads, Ink-Jet Heads, Microdisplays, Optical Switches, and Accelerometers

Read-Write Heads

Read-write (RW) heads still represented around 51% of the MEMS market in 2009: although the traditional application of RW heads in PCs will grow only moderately, the RW market is experiencing a renaissance in consumer electronics, as hard discs are entering music players (e.g., in many iPod models) and smart phones (Samsung introduced the first cell phone with HDD in 2004), as well as digital video cameras, set-top players, and DVD recorders. Memory read/write technology is an area where MEMS will continue to contribute and astound with its results; an important example we encountered in this regard is the IBM thin film read write head and the millipede (see Volume II, Figure 2.4, and Figure 1.1d, this volume). Major U.S. players in this market segment are Seagate, Conner, IBM, Read-Rite, and Applied Magnetic, in Asia there are companies like Yamaha, TDK, Alps, and a few others. Global revenues from shipments of HDDs were expected to reach $27.7 billion in 2010, up 18.4% from $23.4 billion in 2009. This represents a 2010 total unit shipment forecast of 674.6 million compared to 549.5 million units in 2009 (http://www.emsnow.com/npps/story.cfm?pg=story&id=42187).

It is important to note though that MEMS will lose a very important market when hard disc drives are replaced by solid-state disc (SSD) memory (flash drives), as both RW heads and accelerometers will fall away.

Ink-Jet Heads

At a greater than 25% share, inkjet print heads represent the largest portion of the total MEMS component market. Ink-jet heads continue to be one of the most profitable markets for MEMS. Cartridges for ink-jet printers were introduced in the early 1980s by HP and Canon. In Volume II, Figure 5.30, we show inkjet-printer heads machined with excimer lasers. As shown in Volume II, Figure 8.21b, some of those printer heads are very sophisticated, combining fluidics (at high temperatures!) with integrated electronics, sensors, and actuators. There are two major types of ink-jet print heads. First are the less expensive and disposable bubble-jet printheads, such as the ones made by HP, Canon, Ollivetti, Lexmark, Xerox, etc. Then there are the more expensive piezo print heads, manufactured by companies like Epson, MIT (in Sweden), Brother (Japan), and Frankotyp-Postalia (Germany). The main new driver for ink-jet heads in the next couple of years is expected to be the printing of digital photos—especially from cell phone cameras—growing at 15% to 20% per year. An important new trend in desktop printers is the integration of nondisposable inkjet heads in the printer instead of disposable print heads in cartridges. After Epson and Canon, HP is now also starting to ship printers with integrated print head. Although this will slow down the growth in units, the value of these nondisposable print heads is 3 to 5 times higher.

As competition in the printer marketplace continues to intensify, manufacturers of MEMS inkjet heads must reduce fabrication costs while improving product performance. The vast majority of inkjet head production in 2008 was on 6-inch silicon wafers, but increasing inkjet heads sizes—and therefore die sizes—as well as a general trend toward larger wafer diameters were expected to shift almost 10% of production to 8-inch wafers by 2010. These MEMS devices require high-quality, high-speed slotting of silicon wafers that are diced into the barrier chips, through which ink passes from the reservoir into the nozzles. Currently implemented MEMS techniques for silicon wafer slotting have a number of drawbacks. Wet etching processes require a mask step, making them both slow and costly, while sandblasting creates holes with conical edges, limiting their diameter and density. Dry laser techniques, although somewhat more effective, typically generate debris and microcracks that hamper device quality and performance. Today, key MEMS technologies to fabricate inkjet-heads include increasing use of deep reactive ion etch (DRIE) and SU-8 resins, but new MEMS manufacturing techniques are being explored. The Synova Laser MicroJet (Volume II, Chapter 5, "Water Jet-Guided Laser Machining," Figure 5.23), for example, overcomes some of the machining challenges, ablating the silicon material quickly and efficiently

without causing any residual damage. In production environments, the Synova water-driven laser has proven superior to competitive approaches, reducing the cutting time to just 2.5 seconds per slot—faster than any previously implemented slotting technique—with no damage.

It is to be expected that the fluidics and their integration with electronics pioneered in this application field will produce rewarding spin-offs in other application areas such as drop delivery systems, micromachined PCR units, etc., for medical/biomedical applications.

MEMS Microdisplays

MEMS microdisplays are the new MEMS blockbuster, and their revenues were expected to overtake inkjet heads in 2009. Millions of DMDs™ were built into projectors (the first one came out in 1996 from InFocus) and big-screen televisions (the first came out in 2002 from Samsung). Microdisplays found their way from projectors and high-definition, large-screen TVs to microdisplays for mobile handsets (e.g., the iMoD—interferometric modulator display—developed at Qualcomm). It was projected that by 2009 MEMS displays would become the second largest MEMS market, after thin-film RW heads (according to the Nexus report).[1] A major advantage for Texas Instruments (TI) is that DLP chips are an exception to the high-volume/low-price rule, typically for all ICs and most MEMS devices: the 2004 asking price for a DLP chip was $400 in 2004; it was estimated at $190 in 2009 (Nexus).[1]

In an imaginative new application of TI's micromirror technology, NimbleGen Systems developed a set-up that enables researchers to fabricate their own DNA arrays without having to go through the expense of making large sets of expensive photomasks as in the case of the Affymetrix system (see Volume II, Figure 8.19 for a schematic of NimbleGen's virtual mask generation system).

Another elegant MEMS display technology, from Silicon Light Machines, Sunnyvale, California (now owned by Cypress Semiconductor), is the grating light valve, or GLV™ (http://www.siliconlight.com/htmlpgs/homeset/homeframeset.html). In this technology, invented at Stanford, closely spaced parallel rows of reflective ribbons are suspended over a substrate. The gap between the ribbons and substrate is one-quarter wavelength, and in the resting state, the ribbons appear as a continuous reflective surface. With an electrostatic voltage pulling down alternate rows of ribbons, light reflected from the pulled down ribbons travels twice the gap or 1/2 wavelength farther than if reflected from the resting ribbons. The ribbons are arranged such that each element is capable of either reflecting or diffracting light. This allows an array of elements, when appropriately addressed by control signals, to vary the level of light reflected off the surface of the chip. This control of light can be analog (variable control of light level) or digital (switching of light on or off). Because a GLV™ device is reflective, it is highly efficient in its use of light. Besides Silicon Light Machines and TI, Samsung and Sony are also manufacturers of digital mirror technology.

In May 2008, Qualcomm MEMS Technologies, demonstrated the first reflective interferometric modulation (IMOD) color Mirasol™ display for mobile phones. IMOD technology requires no backlighting and reflects light so that wavelengths interfere with each other, creating pure, vivid colors. Mobile devices such as mp3 players and mobile phones stand to benefit from Mirasol displays, which require significantly less power and harness ambient light sources to automatically scale for optimal viewing in virtually any lighting condition. The interferometric modulator element (IMOD) is a simple MEMS device that is composed of two conductive plates. One is a thin-film stack on a glass substrate, and the other is a reflective membrane suspended over the substrate. There is a gap between the two that is filled with air. The IMOD element has two stable states. When no voltage is applied, the plates are separated, and light hitting the substrate is reflected as shown in Figure 10.61. When a small voltage is applied, the plates are pulled together by electrostatic attraction and the light is absorbed, turning the element black. This is the fundamental building block from which Qualcomm Mirasol™ displays are made (Figure 10.61).

MEMS obviously figures central in various designs for next-generation flat panel displays. Illustrative is also the thin-film field emitter work from Capp Spindt (the author's first mentor in MEMS at SRI

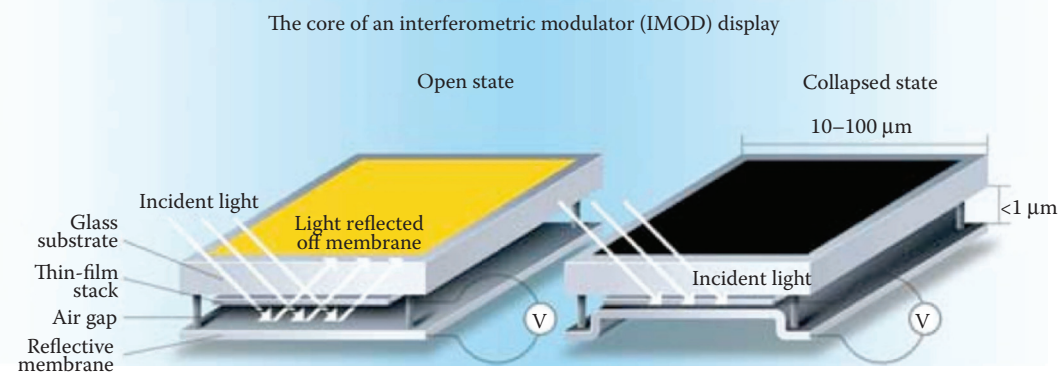


FIGURE 10.61 Interferometric modulation fundamental building block from which Qualcomm Mirasol™ displays are made (http://www.qualcomm.com/qmt/).

International), which is illustrated in Volume II, in Chapter 7, Figure 7.90.

Optical Switches

IC-based processing techniques have been used for a long time in the fabrication of complex optoelectronic ICs, and MEMS has been employed in the fabrication of simple fiber alignment devices. Passive alignment devices such as V-grooves are either fabricated in polymer or Si, with the polymer embodiments enabling high-volume manufacture of low-cost components. The newest developments in optical telecommunications require a new generation of additional components, including the following:

- Wavelength filters
- Micromirror-based all-optical switches
- Configurable add/drop multiplexers to add or drop signals to generate thousands of different frequencies of light
- Tunable filters
- Multiplexers and demultiplexers that direct multiple light beams onto one fiber
- Stabilized optical sources
- Optical polarization controllers
- Integrated optical pumps and MOEMS amplifiers for attenuation, dynamic gain equalization, and dispersion compensation

MEMS is expected to play a role in the manufacture of several of these optical devices. Here we reiterate briefly the role MEMS is playing in just one such application, i.e., large optical switches for telecommunications. As we remember from earlier in this chapter (see under Preamble on the MEMS Market), this application unfortunately led to the so-called *MOEMS bubble* in 2001–2002.

Miniature optical switches, optical cross-connects (OXCs), were expected to change how data are transmitted in everything from communication systems to computers. Miniaturization methods enable the creation of arrays of very small, high-capacity optical switches (see Example 4.4, "Self-Aligned Vertical Mirrors and V-Grooves for a Magnetic Micro-optical Matrix Switch"). These optical switches provide a way of routing light paths from one fiber to another without converting the signals to the electronic domain. OXCs seemed to have arrived at just the right time; optical fiber cables connecting network hubs were indeed quickly outpacing the capacity of electronic switches, and this electronic bottleneck could be solved by this new generation of MOEMS switches. Four example approaches to optical switching are illustrated in Figure 10.62: mechanical (bending of an optical fiber) (a), planar waveguides (where heaters and Peltier devices change the index of refraction to cause the beam path to shift) (b), moving mirror types (c), and the bubble approach (bubbles deflect the light between criss-crossing waveguides) (d).

The router developed at Lucent, for example, could switch 256 input light beams to 256 output fibers without any intermediate optical-electrical conversion (Figure 10.63). Supporting 256 wavelengths, each carrying 40 Gbit/second of traffic, this corresponds to an aggregate throughput of more than 10 Tbit/second. Tiny double-hinged mirrors are used to redirect optical signals by adjusting the mirror tilt.

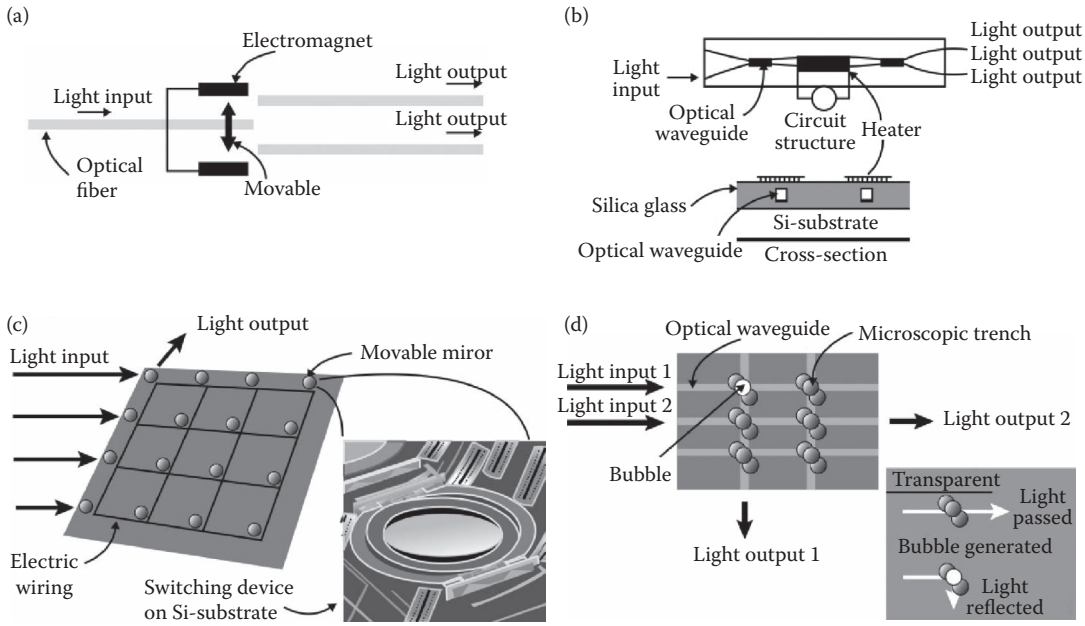

FIGURE 10.62 Example principles of optical switching devices. There are four major principles of operation involved. (a) The mechanical type, where the optical fiber is bent with an electromagnet to change the direction of the light beam. (b) The planar optical waveguide, where heaters and Peltier devices are located near the optical waveguide to change the waveguide temperature. When the temperature changes, so does the index of refraction, causing the beam path to shift. (c) The mirror type. The angles of micromirrors are changed to select different light paths. Mirrors may move on one axis (two-dimensional) or two (three-dimensional). (d) The bubble approach. An oil-filled wall is created along the light path, and bubbles are generated there to reflect the light beam.

A first application for these new switches was expected to be in dense wavelength division multiplexing (DWDM). To squeeze more traffic into a network, one of the strategies is to deploy DWDM. A programmable DWDM add/drop node "drops" one or more wavelengths out of a multiwavelength channel and reroutes them to a different destination while potentially "adding" traffic from another source to the channel.

One of the most impressive optical switches was a 1152 × 1152 OXC by Xros (bought by Nortel and now defunct). The product was projected to be on the market in 2001. Another player was Ilotron a spin-off company from the University of Essex. Most major players in MEMS optical switching were backing the traditional micromirror approach, but Agilent Technologies has a fluidic approach based on its ink-jet technology. In the Agilent switch, bubbles deflect the light between criss-crossing waveguides, and at Corning, liquid crystals are used. In Table 10.12, the four most popular optical switch approaches are compared.

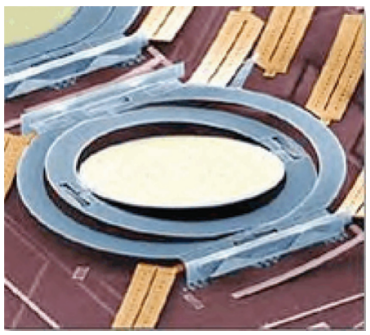

FIGURE 10.63 Lucent free-space microelectromechanical system optical cross-connect mirrors with two-axis, gimbal-mounted micromirrors.

It was expected that optical switches would achieve full commercialization by 2004. The great promise that these truly enabling MOEMS devices seem to offer was at first validated by the acquisition of a series of MOEMS companies. Among these were XROS (a 95-person company), acquired by Nortel Networks for $3.25 billion in stock; IntelliSense, 67% of which was acquired for $500 million by Corning; and Cronos Technologies, acquired for $750 million in stock by JDS Uniphase. However, as we explained in the beginning of this chapter, the more than 10 billion dollar investment by these large telecommunication companies in 1999–2000 became a textbook example of "irrational exuberance." There

Table 10.12 Major Characteristics of Optical Switching Devices

Type	Maximum Channels	Switching Time	Insertion Loss	Cross-Talk (Interference with Other Channels)	Device Dimensions	Manufacturers
Mechanical	1 × 2 to 2 × 4	10 milliseconds or less	0.3 dB	–65 dB or less	Two switches in 8.3 mm × 15.6 m × 28 mm	Hitachi Metals, Seiko Instruments, etc.
Planar waveguide	16 × 16	10 milliseconds or less	8 dB for an 8 × 8 switch	–50 dB or less	10 cm square	NTT, etc.
Mirror	256 × 256	About 50 milliseconds	Unknown	Unknown	Mirrors about 500 μm in diameter	Lucent Technologies, A&T, Japan Aviation Electronics, etc.
Bubble	32 × 32	10 milliseconds or less	0.07 dB per trench	–60 dB or less	2 cm square	NTT Electronics, Agilent Technologies, etc.

were not enough customers for the more than eighty start-ups, and the three largest investing companies pulled back. What was left of the all-optical switching market, in the period between 2002 and 2004, was littered with the broken shells of startups that often tried to survive by doing MEMS foundry work. Today, some surviving MOEMS companies, building all-optical switches, are successfully targeting more modest switch applications; say, for apartment buildings or university switchboards, and for new emerging applications such as semiconductor test equipment. Companies such as Glimmerglass claim to have solved the problems previously associated with the MOEMS switches and maintain that their optical switches are more reliable, less complicated, and more cost-effective. The Reflexion eighty-switch pack from Glimerglass is available as either a small core module tailored for communications-systems manufacturers or as a larger evaluation system. The evaluation system includes the Reflexion module, as well as optical-channel power monitors, a fiber patch panel, and an ethernet* control interface. It is all packed into a 4.5- by 9.5- by 7.0-inch rack-mountable case that consumes just 20 W (see Figure 10.1).

As we saw above, instead of switching signals among very large arrays of fiber optic cables for telecommunication switches, TI targeted its digital light processing (DLP) technology to projectors and video displays. Because it focused on the right mass consumer application from the get-go, TI's digital micromirror device (DMD) turned out to be a big-scale MEMS success (see above).

Today, even the large all-optical optical switches are back. Late-stage startup Lambda OpticalSystems (Reston, VA), for example, recently unveiled the LambdaNode 2000, an integrated optical-switching and DWDM transport platform. The system supports 256 wavelengths, each wavelength running at 10 Gbit/s for a total capacity of 2.5 Tbit/s. The device is running live traffic today in a 10-Gbit/s transcontinental network built by the U.S. Naval Research Laboratory. Also, Calient Networks announced details of an interoperability demonstration it conducted with Cisco Systems.

Accelerometers

Recently, the market for accelerometers in consumer electronics (CE) (computers, games, phones, etc.) has also started to explode. Consumer electronics have the potential to dwarf the automotive application, not only of accelerometers but also of pressure sensors and gyros. The first accelerometer application in consumer electronics was for hard drive protection in notebooks. IBM (now Lenovo) puts a dual-axis accelerometer in its notebook: the accelerometer detects falling motion and places the HDD in safe mode prior to impact. Samsung (and others) have experimented with motion-based applications in handsets (gaming, user interfaces, power management, navigation). Early in 2007, Apple announced the iPhone, with motion-based features.

* Ethernet: LAN (local area network) connects your computer to computers close by and around you.

Consequently, MEMS growth is expected by some to follow a hockey stick curve, with the value of products rising to $40 billion in 2015 and $200 billion in 2025.[99] (See also an estimate by Dr. Marinis from Draper Laboratory: http://www.sem.org/PDF/s01p01.pdf.) The problem is now one of profitability rather than the absence of real product opportunities: how to earn money on, say $0.32 microphones or $1.35 triaxis accelerometers for mobile handsets? Only by becoming more similar to the IC industry can MEMS devices achieve this goal, i.e., through more integration on larger (8-inch) Si wafers. In a sense, as far as mechanical and MOEMS are concerned, the IC industry has now swallowed the MEMS field.

RF-MEMS

Wireless communications is showing an explosive growth of emerging commercial and consumer applications of radiofrequency (RF), microwave, and millimeter-wave circuits and systems. Just think that the number of mobile phones was predicted to reach 4.6 billion in 2010 (http://www.cbsnews.com/stories/2010/02/15/business/main6209772.shtml). Several of the new and improved functionalities in mobile phones will be enabled by the use of MEMS products, such as microphones, lenses, and miniaturized data and energy storage devices. Analyst Bourne predicts that by 2010, three-quarters of all cell phones will benefit from MEMS (http://www.eetimes.com/electronics-news/4071288/MEMS-exec-sees-billion-dollar-markets) in 2009. This is making the consumer industry more and more the driving force behind many technology developments in MEMS. RF-MEMS will help further reduce the mobile phone size, power consumption, and cost. According to a market study from WTC covering the 2005–2009 period, the market for RF MEMS components was $126 million in 2004, confirming WTC's forecast from 2002. It was forecasted to grow to over $1.1 billion in 2009 (Figure 10.64).

In this application area, a situation has been reached where the presence of the expensive, off-chip passive RF components, such as fixed capacitors and tunable capacitors (varicaps), high-Q inductors, RF switches and filters, plays a limiting role. MEMS promises to provide higher levels of integration at lower costs and reduce the power consumption. In RF-MEMS the compatibility of the MEMS process with active circuitry processing is critical, and the ideal MEMS solution must have little if any impact on the wafer/electrical yield of the active circuitry. This capability will enable component suppliers to offer increased performance designs while maintaining or reducing device cost. An additional benefit of the totally integrated approach is the inherent reliability of the IC-based processing. One approach is the innovative "above-IC" (AIC) technology that enables the placement of RF-MEMS devices directly on top of the IC by using a thick copper technology compatible with CMOS, BiCMOS and gallium arsenide processes.[100] Over time, integration of RF-MEMS devices may be the means to replace all passive RF chips with on-chip devices, achieving the long-awaited single-chip RF solution. Current technology and process limitations prevent replacement of all passive components with on-chip MEMS components. But placing even some components on-chip offers significant space and cost savings, allowing smaller form factors, benefiting cell phones for example, or added functionality such as internet connectivity.

Commercially available MEMS-based switches (e.g., from Raytheon), with low-loss metallic structures for lower insertion losses and higher linearity, achieve actuation by using either electrostatic or electromagnetic techniques. Infineon, for example, is aiming for electrostatic switches with 10- to 100-microsecond switching times. Electrostatic actuation consumes no current but requires higher actuation voltage (>10 V), whereas electromagnetic actuation requires a lower actuation voltage, but its current consumption is significantly higher (see Chapter 8, this volume). The use of magnetic thin films introduces slightly more processing complexity. Electrostatic switches offer the most promise as reconfiguration switches (e.g., antenna switches or frequency band selection switches), where the key factor is low power consumption.

MEMS manufacturers are also fabricating inductors using a thick copper-on-insulator process to achieve higher quality factors and resonant frequencies. Similarly, vendors are fabricating MEMS-based

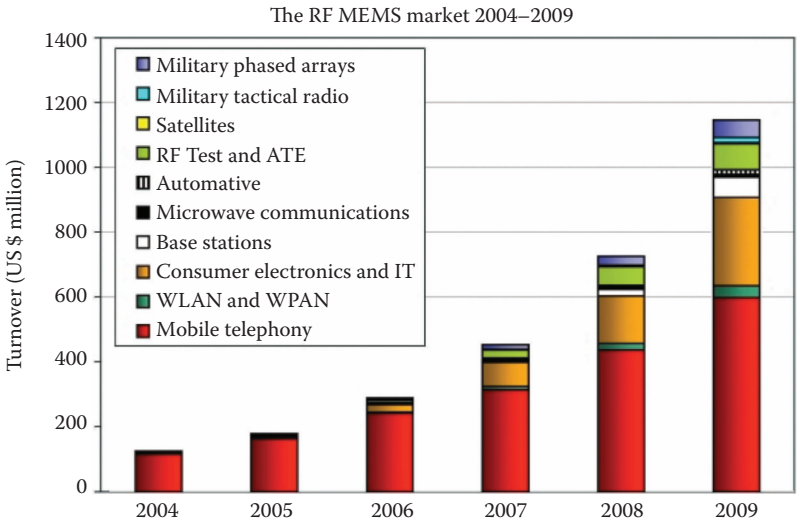

FIGURE 10.64 Radiofrequency microelectromechanical systems in wireless communication for the period 2004–2009 (WTC).

variable capacitors by using a thick copper-on-insulator process to minimize the ohmic losses. MEMS inductors and capacitors are typically suspended with a small air gap insulating them from the lossy silicon or GaAs substrates. The manufacturers achieve tunability of these components by using movable metallic structures with actuation processes similar to the ones used for switches. Typically, the quality factor of inductors using silicon technology have been less than 10 at 2 GHz, so far; this means that most applications have still required off-chip inductors to realize high-performance RF circuits. The objective remains to improve the quality of these devices and the tunability range of the circuits. MEMSCAP has designed high-quality inductors from thick copper on insulator; they range from 1.5 to 15 nH.[101] A quality factor of between 50 and 80 at 2 GHz was obtained. Variable capacitors from the same group offer a high tuning range of more than 2.5, with values ranging between 1 and 10 pF. The combination of inductor and capacitor capabilities optimized for low loss and flexible tunability range is important for the design of voltage-controlled oscillators (VCOs) and filters. Currently, foundries making on-chip RF-MEMS devices are aiming toward fabrication of all the RF-MEMS device types at the same time.

In Volume I, Chapter 4, we saw that for wireless networks such as Wi-Fi and Bluetooth, SiGe is becoming an important choice substrate (see also Chapter 5, this volume where we compare GaAs with SiGe). An example SiGe process is the 130-nm SiGe BiCMOS technology from Jazz Semiconductor. This process combines industry standard 130-nm CMOS with 200 GHz silicon-germanium (SiGe) heterojunction bipolar transistors (HBT) NPN transistors for high-performance RF and millimeter-wave ICs. This technology enables the design of the highest performance circuits in advanced high-speed optical, wireless, and millimeter-wave applications.

Currently, the bulk of the RF-MEMS market services mobile telephony applications, with bulk acoustic wave (BAW) (see Chapter 8, Figure 8.18) duplexers and filters supplied largely by Agilent and Infineon (this product was predicted to continue to dominate and constitute around 40% of the total market in 2009). The RF-MEMS market earned $330 million in 2006, with three companies shipping the newer FBAR (Figure 8.19) duplexers and filters: Avago, Infineon, and EPCOS.

Knowles Acoustics shipped 200 million surface-mount MEMS microphones (a two-chip solution in a single package) and confirmed its clear leadership in this sector, doubling its estimated revenues to $92 million for 2006. Knowles has been selling to cell phone makers for five years and is by far the biggest player in MEMS cell phones. MEMS Tech of Malaysia is a close second. Akustica, Sonion MEMS, and Infineon are other entrants in this area. Today, Akustica is the only maker of a single-chip MEMS microphone, and its rival Sonion MEMS A/S (Roskilde, Denmark) was set to begin volume shipments of MEMS microphones from its new

production facility in Ho Chi Minh City, Vietnam, in 2008. Akustica puts all the functions of a miniature electret condenser microphone—including a discrete FET, a separate operational preamplifier chip, and an A/D converter chip—onto a single CMOS MEMS microphone chip.

Another mass market emerged for consumer and IT applications in 2006–2007 with micromechanical resonators. Silicon MEMS start-up companies Discera, Silicon Clocks, and SiTime are currently trying to displace quartz from the oscillator market. They are building packaged silicon MEMS oscillators, consisting of a MEMS resonator and the electrical circuits for the oscillator function and for frequency and temperature compensation. Here, micromechanical resonators are used not as filters but rather as timing devices. MEMS oscillators sales started at the end of 2006 with the first million shipments by SiTime. Seiko Epson also started to ship its QMEMS oscillators. RF-MEMS switches were only in the sampling phase in 2006 (e.g., at Teravicta and Panasonic) but were jolting the market, with Teravicta shipping 10,000 units per month and plans to reach the million mark by the end of 2007. In Chapter 5, "Quartz Properties and Quartz Machining," we made a detailed comparison of Si oscillators with quartz oscillators. More than sixty companies are currently involved in RF MEMS manufacturing, and around a quarter of them were shipping commercial products or samples in 2005. Outside of mass markets, RF test and automated test equipment (ATE) offer the best opportunities, followed by military applications (see Figure 10.64).

MEMS Foundries

As we remarked earlier, the emerging MEMS consumer market is a strong driving force for the MEMS industry to develop MEMS devices integrated with ICs and is pushing the MEMS industry to even adapt 8-inch wafer size manufacturing. Capital requirements for a MEMS production line can be very, very large. And, as with semiconductors, the smaller the features, the more expensive the production line is. Many MEMS startups expended plenty of investor dollars wrestling with exotic materials and getting pilot production lines in place, exhausting their funds before their markets could develop. With this knowledge and the current MEMS upswing, even foundries are now becoming profitable. Along this line, Bosch, a MEMS pioneering company, founded a subsidiary named Bosch Sensortec in early 2005. This subsidiary is dedicated to engineering, developing, and marketing micromechanical sensors with foundry services for consumer electronics, medical technology, security systems, and logistics. The firm is backed by Bosch automotive MEMS development and production and owns a 4000-m^2 CMOS fab and a 4200-m^2 MEMS back-end fab. A new 8-inch fab was planned for 2009. The need to adhere closer to IC manufacturing rules has become even more urgent as few U.S. MEMS foundries have survived. As mentioned earlier, the MEMS foundries that did survive the MOEMS bubble can expect to be doing good business if they can scale up to compete with traditional IC fabs fast enough. In the author's own experience, MEMS foundries are hard to make profitable in the United States, as they need to keep on accepting a wide variety of jobs to keep the expensive clean-room operation going. In the process they do not stay long enough on the learning curve of one new product to become world leaders for that particular product. As a consequence, these labs are moving more and more to Asia, where a large company might have more patience to keep the doors open till the MEMS foundry turns profitable. Olympus, in Japan, for example, already runs the largest MEMS foundry in the world.[102]

Nanotechnology Markets

Introduction

As is clear from the preceding section, although not as large a market as projected, MEMS has made a successful transition out of the laboratory into the marketplace. If one excludes the contributions to nanotechnology markets from genetic engineering (e.g., genetically engineered proteins and DNA probes) and the latest ICs (e.g., chips with sub-100-nm critical dimensions that started shipping in 2003) and next-generation lithography equipment (e.g., extreme UV lithography exposure stations), nanotechnology (NEMS) is still in its infancy, and when a new field emerges it is often the tool-makers

and the conference organizers/consultants who make the most money. In his entertaining treatise on Nanotech Pioneers, Steven Edwards[103] compares this to the California gold rush, when the hardware stores and whorehouses made more money than the miners themselves. Nanotechnology quickly became a buzzword and a catchall term to attract funding, and as in the case of MEMS, many existing activities have been relabeled to raise their stock market value.

Whereas in MEMS, products/markets do exist (Bosch makes >100 million MEMS devices a year), in NEMS we deal mostly with manufacturing gear (e.g., carbon-nanotube chemical vapor deposition, dip-pen lithography, nanoimprint lithography, etc.), metrology equipment (Veeco's SPM, Zyvex Nanomanipulators, etc.), software (e.g., Atomostix, MEMulator™, etc.), and products based on nanomaterials (e.g., nano skin cream, suntan lotions, nano-enhanced tennis balls that bounce longer, etc.). Some market studies do also count nanodevices and next-generation lithography equipment in their market estimates. We advice against this practice, as co-opting the IC industry in nanotechnology market projections is bound to be misleading. The emphasis should be put on innovative nanofabrication methodologies making new nanomaterials and nanoproducts and not co-opting efforts that have been going on for a long time. Some will argue that, today at least, besides nanotools research tools, this leaves only low-tech nanomaterials-based products as a new realization. These are products with little technology content and scant manufacturing innovation, and cynics would say that a new transparent sunscreen hardly justifies the current level of investment in nanotechnology.

As with any exciting topic, there is a lot of speculation and exaggerated estimates about the impact nanotechnology will make over time. This author does believe that the ultimate impact of nanotechnology will be broader and deeper than the IC revolution ever was. This is because of the potential of nanotechnology to apply material innovations to so many different situations and challenges. Nanotechnology will profoundly change major industries such as electronics, medicine, transportation, defense, and consumer goods through the development of advanced materials that are lighter, stronger, and more versatile than existing materials. The current nanomaterials boom will be followed by a nanodevices upsurge—it just might be much slower than current market studies suggest.

Overall Market and Market Character

The National Science Foundation (NSF) projects that nanotech will be a $1 trillion industry by 2015; the accuracy of this claim is difficult to assess given the doubts expressed above about what is included in this estimate. Many policy makers have bought into this projection, though; governments across the world poured $4 billion into nanotech research in 2004, and in 2006, the worldwide investment in nanotech research and development was said to be $12.4 billion. There is even a stock index of public companies working on nanotechnology (launched by Lux Research in 2005).

According to a technical market research report, "Nanotechnology: A Realistic Market Assessment" from BCC Research (http://www.bccresearch.com), the global market for nanotechnology was worth $11.6 billion in 2007. This was expected to increase to $12.7 billion in 2008 and $27.0 billion by the end of 2013, with a compound annual growth rate (CAGR) of $16.3% (see Figure 10.65) This makes the NSF market projection for 2015 ($1 trillion) seem unrealistically high. However, as a counterpoint, Lux Research estimates that by 2014, $2.6 trillion in manufactured goods will incorporate nanotechnology—or about 15% of the total global

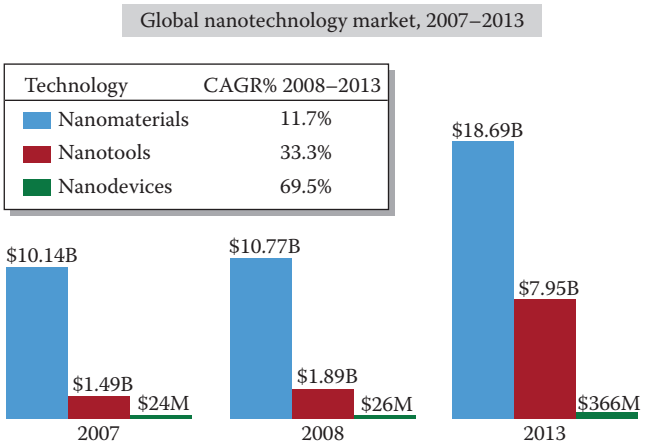

FIGURE 10.65 Global nanotechnology market, 2007–2013. (From BCC Research.)

output will be nanotechnology based! It is hard to figure out what this Lux Research number really means though in terms of the real nanotechnology market size (e.g., TiO_2 and ZnO nanopowders are cheap and would not really constitute a big market share or put many people to work). We actually believe that even the BCC Research numbers are too high. This research firm breaks down the market into nanomaterials, nanotools, and nanodevices. As stated above we are uncertain about the merit of including nanodevices in a nanotechnology market study as today the only nanodevices on the market are the next-generation ICs. These are based on the traditional top-down manufacturing methodologies that were ongoing long before and independent of the current nanofocus. More critical, in terms of coming up with acceptable numbers, is the unfortunate inclusion of current next-generation lithography (NGL) equipment in a market study that should be projecting the impact that new nanotechnologies are bound to make. By including NGL equipment one runs the risk of making projected numbers a self-fulfilling prophecy by broadening the definition of what passes for nanotechnology (this is what happened in the MEMS field). Such work will also not provide sufficient information in order to guide corporate or individual investment decisions. Investors require additional data, such as the size of specific nanotechnology markets, novelty of the manufacturing method (e.g., is it evolutionary or revolutionary), prices, and competition, as well as potential regulation. Nanotechnology market reports should point out specifically whether one is just dealing with an evolutionary extension of IC fabrication or with a revolutionary new nanofabrication method (there are plenty of sophisticated market reports covering the future IC market separately).

Of the three BCC Research nanomarket categories, nanomaterials dominated in 2007, accounting for 87% of the market. Worth an estimated $10.8 billion in 2008, this segment was projected to reach $18.7 billion in 2013, for a CAGR of 11.7%. Nanotools accounted for 12.8% of the market in 2007. Worth an estimated $1.9 billion in 2008, the segment was predicted to reach almost $8.0 billion by the end of 2013, for a CAGR of 33.3%. Nanotools, in which BBC Research includes the nanolithographic tools used to produce the next generation of semiconductors, are projected to grow at a much faster rate than nanomaterials. As a result, that market share was predicted to increase to 29.4% in 2013, while the nanomaterials' share would fall to 69.2% of the total market.

The nanodevices segment, according to BCC Research, will enjoy a CAGR of 69.5% between 2008 and 2013. It was expected to increase from a $26.2 million segment in 2008 to $366.2 million by the end of 2013.

The largest end-user markets for nanotechnology in 2007, according to BCC Research, were environmental remediation (56% of the total market), electronics (20.8%), and energy (14.1%). Electronics, biomedical and consumer applications have much higher projected growth rates than other applications over the next five years (i.e., 30.3%, 56.2%, and 45.9%, respectively.) In contrast, energy applications are projected to grow at a CAGR of only 12.6%, and environmental applications should actually decline by an average of 1.5% per year. It is not clear to this author why this should be the case. Depending on government policies on green technologies, the real numbers might again be quite different.

While it appears inevitable that nanotechnology will have a broad and fundamental impact on many sectors of the world economy, various technical, marketing, and other hurdles need to be overcome before nanotechnology fulfills this promise. These challenges and differences of opinion regarding the speed of the commercial implementation of new nanoproducts are reflected in the wide divergence among existing estimates of the U.S. and global nanotechnology markets. Global market estimates for 2004–2005, for example, range from $8 billion to $68 billion.

Polls show that most Americans know little or nothing about nanotechnology, despite the fact that, according to some estimates, nanotechnology was already incorporated into more than $50 billion in manufactured goods in 2006. Public perceptions about risks—real and perceived—can have large economic consequences. How consumers respond to these early products—in food, electronics, health care, clothing, and cars—is a litmus test

for broader market acceptance of nanotechnologies in the future. Along with high expectations, nanotechnology also evokes fear in some people. Bill Joy, cofounder of Sun Microsystems, published an article in 2000 in which he called nanotechnology (along with biotechnology and robotics) a "Faustian bargain" and a "Pandora's box," and called on mankind to relinquish all three technologies. In 2002, Michael Crichton's novel *Prey*, a fictional treatment of the dangers of nanotechnology, made the *New York Times* bestseller list. Interestingly, a recent nationwide survey conducted by the University of Wisconsin–Madison indicates that scientists are more concerned than the general public about the potential health and environmental risks of nanotechnology. Over 30% of scientists interviewed expressed concern that nanotechnology may pose risks to human health, whereas only 20% of ordinary people shared their fears (because they do not understand the technology?).

An important event that helps us appreciate the nanotechnology market dilemma today is what happened to Nanosys in 2004. On April 23 of 2004, Nanosys Inc., a Palo Alto-based developer of inorganic semiconductor nanocrystals, filed for an initial public offering (IPO). Merrill Lynch, Lehman Brothers, CIBC World Markets, and Needham & Co. were underwriting the offering. The company was seeking to raise up to $115 million on the Nasdaq market. But on August 4, 2004, Nanosys Inc. withdrew its IPO. "Based on adverse market conditions," the company explained "Nanosys has determined that it is not advisable at this time to proceed with the proposed offering." Press reports leading up to the IPO had lambasted Nanosys for having only $3 million in revenues in 2003. It was also pointed out that one of the few hard metrics available to value the firm—a price-to-revenue ratio over 120—suggested it was a speculative investment, and that if it performed poorly, it would undermine the ability of other nanotechnology firms to access the public markets. One must also realize that in 2004, the MEMS technology bubbles of 2001–2002 were still vividly remembered.

Nanosys later did raise approximately $40 million in a private equity financing. This financing was led by El Dorado Ventures and includes new investors Masters Capital, Medtronic, Inc., Wasatch Advisors, and others. In addition, there was strong participation from existing investors, including Alexandria Equities, ARCH Venture Partners, CDIB BioScience Ventures, CW Group, Harris & Harris Group, Inc., In-Q-Tel, Intel Capital, H. B. Fuller Company, Lux Capital, Polaris Venture Partners, Prospect Venture Partners, UOB Hermes Asia Technology Fund, and Venrock Associates. Nanosys is using this funding for the ongoing development and manufacturing scale-up of products that incorporate its proprietary, inorganic nanostructures with integrated functionality for multiple industries. Current product development programs include chemical analysis chips for pharmaceutical drug research, fuel cells for portable electronics, nanostructures for displays and phased array antennas, nonvolatile memory for electronic devices, and solid-state lighting products.

The type and number of California-based MEMS and NEMS start-up companies (see Table 10.13) has historically played an important role in what happens in these areas worldwide. In 2000, according to Janusz Bryzeck, there were 100 MEMS/NEMS-based companies in California alone, 33 of which were fabricating MOEMS devices. Decimated by the MOEMS bubble of 2001, "only" sixty-five California MEMS/NEMS companies survived in 2005. In the early years (say, from 1972 on), companies making mechanical MEMS devices (using wet bulk micromachining) played a pivotal role in the development of the market for these mechanical Si sensor products. Petersen's 1982 paper extolling the excellent mechanical properties of single-crystalline silicon helped galvanize academia's involvement in Si micromachining in a major way.[104] Before that time, timid efforts had played out in industry, and practical needs were driving the technology (market pull). Academics often explored micromachines that constituted gadgetry only, and, as a consequence, the field was perceived by some as a technology looking for applications (technology push). Polycrystalline surface micromachining-based (see Volume II, Chapter 7) MEMS companies started emerging around 1991. However, from the mid-1990s on, many of the MEMS companies became bio-MEMS oriented (application of MEMS to biotechnology), and single-crystalline and polycrystalline Si were often not the

TABLE 10.13 Some California Microelectromechanical System/Nanoelectromechanical System Companies

Company	Location	Date	Overview of Activity and Manufacturing Method
Sensym	Milpitas	1972	Made sensors from silicon and piezoresistive materials. Some cavities in products made by anisotropic etching. *Source:* U.S. Patents.
Endevco	San Juan Capistrano	1975	Produces sensors for vibration, shock, inertial motion, and dynamic pressure measurement using semiconductor technology and piezoceramic processing techniques. *Source:* Endevco.
Irvine Sensors Co.	Costa Mesa	1980	Manufactures some products in a batch process. Products are layered silicon and connected with gold. *Source:* Irvine Sensors Co.
Komag	San Jose	1983	Komag sputters thin-film disks using a vacuum deposition process. During the sputtering process, microscopic magnetic layers are successively deposited on the disk—these layers ultimately provide the magnetic storage capacity for data. *Source:* Komag.
Nanostructures	Santa Clara	1988	Produced thin films such as silicon membranes by electrochemical means or mask production with RIE. *Source:* U.S. Patents.
Abaxis	Sunnyvale	1989	Produces point-of-care blood analyzers from a bottom- and mid-layer of polymethymethacrylate plastic with a top layer of ABS made in a molding process. Some products made from joined thermoplastics through melting. *Source:* U.S. Patents, Abaxis.
Sentir	Santa Clara	1991	Produced sensors, including a pressure sensor made on a ceramic substrate with piezoresistive diaphragm and gel as the transfer medium to transducer. *Source:* U.S. Patents.
Affymetrix	Santa Clara	1992	The company's microarrays were made by a process that begins by coating a 5" by 5" quartz wafer. *Source:* Affymetrix.
Unisun	Newbury Park	1993	Unisun's techniques provide substantial cost advantages to traditional PV products based on silicon wafers and to vacuum deposition techniques typically used to deposit PV thin films. *Source:* Unisun.
Nanogen	San Diego	1993	Makes microarray cartridges the only Si based DNA arrays ever made. *Source:* Nanogen patents.
Front Edge Technology	Baldwin Park	1994	FET develops, manufactures, and markets next-generation, ultra-thin rechargeable batteries for card-type applications. *Source:* Front Edge Technology.
Aclara	Mountain View	1995	Some products made by thermally bonding plastics. *Source:* U.S. Patents.

(Continued)

TABLE 10.13 Some California Microelectromechanical System/Nanoelectromechanical System Companies (Continued)

Company	Location	Date	Overview of Activity and Manufacturing Method
Nanochip	Fremont	1996	Nanochip is developing the next generation of removable, portable memory chips for consumer applications. Using MEMs technology along with arrays of atomic force probe tips, Nanochip is developing storage chips that will store tens of gigabytes per chip. Our technology is not bound by lithography constraints. *Source:* Nanochip.
Caliper	Mountain View	1996	Microfluidic lab-on-a-chip made of quartz, glass, or plastic-bonded to each other. *Source:* Caliper.
Cepheid	Sunnyvale	1996	Made sample preparation products with the process of electrodeposition, LPVD, glass bonding, and RIE out of materials from the semiconductor industry. *Source:* U.S. Patents.
Fluidigm	South San Francisco	1997	Fluidgm's NanoFlex valve consists of a membrane that deflects under pressure to pinch off the flow of fluids in a microchannel. The valve is made from two separate layers of elastomeric rubber. *Source:* Fluidigm.
Carbon Solutions	Riverside	1998	Manufactures single-walled carbon nanotubes (SWNTs) in bulk quantities. *Source:* Carbon Solutions.
Zyomex	Hayward	1998	Products included fluidic technologies using an etching process. *Source:* U.S. Patents.
PolyFuel	Mountain View	1999	PolyFuel's membranes are based upon hydrocarbon polymers rather than fluorocarbon. *Source:* PolyFuel.
GeneFluidics	Monterey Park	2000	GeneFluidics disposable cartridges and sensor chips are injection-molded, using only plastic substrates and other low-cost materials; the GeneFluidics platform will dramatically reduce the cost of molecular analysis.
Molecular Nanosystems, Inc.	Palo Alto	2001	The company synthesizes carbon nanotubes on predefined locations with the desired orientation on different substrates, manipulates the properties of carbon nanotubes via functionalization, and integrates them into next-generation gas and biological sensors and other high-end electronics devices. *Source:* Nanovip.
Discera	San Jose	2001	Discera offers PureSilicon resonators, which is displacing quartz crystal solutions with systems-on-a-chip alternatives. *Source:* Discera.

Ahwahnee Inc.	San Jose	2002	Ahwahnee's industry-leading CNTs are revolutionizing a number of markets, including fuel cells, energy, and semiconductors. *Source:* Ahwahnee.
Apex Nanomaterials	San Diego	2003	Apex Nanomaterials's world first-class SWNT production technologies using both arcing and CVD methods are generating SWNTs with the best quality and most cost-effective at an industry scale. *Source:* Apex Nanomaterials.
Atomate	Santa Barbara	2003	Atomate Corporation develops complete systems, components, and materials that are optimized for the synthesis of nanostructures using CVD.
NanoSensors, Inc.	Santa Clara	2003	Develops and markets sensors and instruments to detect explosive (X), chemical (C), and biological (B) agents ("XCB") *Source:* Nanosensors.
InvenSense	Santa Clara	2003	InvenSense's gyroscopes takes advantage of major innovations in MEMS mechanical design and fabrication, mixed-signal ASIC design, and wafer-level packaging, which is based on the IC industry. *Source:* Invensense.
Intelligent Optical Systems, Inc.	Torrance	2004	Develops cutting-edge technologies in optical sensing and instrumentation. Current research and development is being conducted in various areas, including Nanoprobes and Materials for Sensing. *Source:* Nanovip.
Unidym, Inc.	Menlo Park	2006	Unidym's initial product is a transparent, conductive film of CNTs that replaces the approximately $1B of expensive and brittle metal oxide films currently employed in touch screens, flat-panel displays, OLEDs, and thin-film solar cells. *Source:* Unidym.
Biodent	Menlo Park	2006	Biodent is the first company to combine printed optoelectronic components with microfluidic systems. This combination is enabled by the fluid processability of organic semiconductor materials. Biodent allows for the first time to print and integrate full optical readout systems directly onto microfluidic devices. *Source:* Biodent.

preferred MEMS substrates for these applications. Later yet, from 1997 on, nanotechnology companies, mostly working on biotechnology type applications (bio-NEMS), started emerging, and here Si was often not involved at all.

For further reading on the history of MEMS and NEMS up to today see Volume I, Chapter 1.

Nanotechnology Tools

To estimate the size and to forecast the market for nanotechnology tools over the next five years, nanotechnology analysis firm Lux Research interviewed CEO's and marketing executives at 21 leading tool vendors worldwide and research and development leaders at forty-nine companies, universities, and national laboratories active in nanotechnology. They correctly excluded established uses of manufacturing and metrology tools in fields such as semiconductors and data storage. This firm believes that the market for tools used to fabricate emerging nanotechnology could grow from less than $20 million in 2004 to nearly $235 million by 2010. At the same time, they claim, the market for metrology tools to inspect matter on the nanometer scale, which currently dominates the $580 million nanotechnology tools market, is expected to see only tepid growth, although still command more than $750 million in 2010. These numbers are lower, and more realistic, than the BCC Research findings (see above) as they exclude the traditional IC tools.

Nanotechnologists basically use three kinds of tools to experiment with matter on the nanometer scale. First, metrology tools, reviewed in Chapter 6, this volume, such as atomic force microscopes (AFMs) and scanning electron microscopes (SEMs) visualize the nanometer-sized objects and represent the most mature and widely used category of tools for emerging nanotechnology. Second, fabrication tools such as nano-imprint lithography and dip-pen nanolithography create structures at the nanometer scale. Thirdly, modeling tools predict nanostructure properties to circumvent the costs and time associated with experiments. Lux Research predicts that the nanotechnology-tools market will see a CAGR of 11% to nearly $1.1 billion in 2010. However, growth will not be even across each of the three market segments. The current market for nanotechnology tools is dominated by inspection tools, which accounted for 95% of the 2004 revenues. The inspection-tools market saw dramatic growth during the early 2000s nanotech explosion, when many university nano centers were being built and equipped. However, the growth outlook for inspection tools looks slow because the university and lab markets are now saturated.

Nanofabrication tools have not yet found commercial use. Still, Lux Research expects these instruments to gain traction over the next five years and move beyond research and development labs to manufacturing floors. In particular, Lux Research sees nano-imprint lithography as the favorite candidate. Lux Research felt dip-pen nanolithography facing sharp resistance, as in many cases researchers would rather have a kit to modify an AFM they already own than purchasing a whole new instrument just to do dip-pen. No wide use for dip-pen nanolithography in production is anticipated before 2010.

Modeling tools claimed less than $10 million in 2004 in the face of entrenched skepticism from potential customers. In five years, Lux Research expects that market to expand to only roughly $40 million, a small fraction of the total nanotechnology-tools market. Still, in a decade the analysts predicted it could break $100 million as power, accuracy, and ease of use of modeling tools continues to improve and more customer success stories emerge.

Nanomaterials

Even though much of the research is still in the initial stages, nanoproducts based on nanomaterials have entered the commercial market. According to an update to the nanotechnology consumer product inventory maintained by the Project on Emerging Nanotechnologies (PEN) (*ScienceDaily*, April 25, 2008), new nanotechnology consumer products are coming on the market at the rate of three or four per week. The number of consumer products using nanotechnology has grown from 212 to 609 since PEN launched the world's first online inventory of manufacturer-identified nanotech goods in March 2006. Health and fitness items, which includes cosmetics and sunscreens, represent 60% of these products. There are thirty-five automotive products in the

PEN inventory, including the Hummer H2. General Motors Corporation bills the H2 as having a cargo bed that "uses about seven pounds of molded in color nanocomposite parts for its trim, center bridge, sail panel and box rail protector." Nanoscale silver is the most cited nanomaterial used. It is found in 143 products, or over 20% of the inventory. Carbon, including carbon nanotubes and fullerenes, is the second highest nanoscale material cited. Other nanoscale materials explicitly referenced in products are zinc (including zinc oxide), titanium (including titanium dioxide), silica, and gold. A list of nanotechnology merchandise—containing everything from nanotech diamonds to cooking oil to golf clubs to iPhones—is available at http://www.nanotechproject.org/consumerproducts. One of the new items among the more than six hundred products now in the inventory is Swissdent Nanowhitening Toothpaste, with "calcium peroxides, in the form of nano-particles." PEN Project Director David Rejeski cites Ace Silver Plus—another of the nine nano toothpastes in the inventory—as an example of the upsurge in nanotechnology consumer products in stores.

There are more than five hundred nanotechnology companies globally, and one-third are in nanoparticles. Of that one-third, more than fifty-five are in carbon nanotubes. Of the present carbon nanotube companies, about twenty are into large-scale production. Some representative example companies in the last category include the following:

1. Nanoledge—(France). Large-scale production (4 ounces per day)—tennis racquets, fibers.
2. Mitsui CNRI (Akashima, Tokyo)—new nanotube plant (120 tons per year at 10% of the present cost).
3. Frontier Carbon (Kitakyusyu City)—Mitsubishi large-scale manufacturing (400 kg per year and 1500 tons in 2007).

Another group of carbon nanotubes companies sells modified carbon nanotubes (e.g., for sensor applications):

1. Carbon Nanotechnologies, the late Richard Smalley's company ($15 million—from angel investors)—single-walled and functionalized tubes.
2. Nantero (>$20 million—DFJ and other venture capital firms)—NRAM™, a high-density, nonvolatile random access memory chip.
3. Molecular Nanosystems Stanford ($2 million—band of angel investors)—nanotube sensors.
4. C Sixty ($4 million—CNI angel investors)—protease inhibitor, anti-HIV (merged with CNI).

Carbon nanotubes and fullerenes have very broad applications, and from the above it is seen that large manufacturing companies are stepping in, with the price of product dropping rapidly. There is also a clear trend of specializations developing (e.g., modified carbon nanotubes). There have not been any IPOs in this area yet. Applications of fullerenes include clothes (carbon nanotubes form waterproof tear-resistant cloth fibers), concrete (carbon fibers increase the tensile strength, and halt crack propagation), sports equipment (stronger and lighter tennis rackets, bike parts, golf balls, golf clubs, golf shaft, and baseball bats), ultrahigh-speed flywheels (the high strength/weight ratio enables very high speeds to be achieved), and bridges.

Other nanoparticles are used in catalysis, ceramics, dug delivery and functional materials, and coatings. Existing companies are Degussa, Cabot Corp, Johnson Matthey BASF, and Altana; start-up companies include the following:

1. NanoPhase Technologies (Nasdaq). Patents licensed from Argonne in 1990. This was the first Nanotech IPO (1998). It was overhyped and had to pay compensation of $4.8 (January 2002). Altana Chemie AG acquired a 7% share for $10 million in 2004. Products include ZnO nanoparticles for sunscreens and catalysts. Losing $1.3 million per quarter.
2. Ntera ($30 million)—was lithium-ion batteries, now nanochromic displays.
3. Nanogram ($6.7 million)—nanomaterials.
4. Aveka (buyout from 3M)—particle processing.
5. Oxonica ($4 million)—sunscreens, bio tags, catalysts. Floated on Aim 2005 (overdiluted).
6. Quantum Dot Corp ($37 million)—bio-assays. Acquired by Invitrogen in October 2005.
7. Nanosphere ($10 million). Gold nanoparticle DNA probes for biothreat detection (anthrax).

8. Qinetiq—nanomaterials.
9. Nanomagnetics—was data storage, now water purification, Apaclara.
10. Nanosys—the hyped nanotech IPO (oversold; see above). A Larry Bock company. Sells as much the technology as brand name scientists (Charles Lieber, Hongkun Park, Paul Alivisatos, and many others over the years). Products include biosensors (functionalized inorganic semiconductor nanowires, 1D electron flow; highly sensitive and selective), photovoltaics, nanocrystals in host matrix, solar cells as roof tiles (Matsushita contract), macroelectronics; flexible, low-cost substrate, nanostructured surfaces, hydrophobic and antimicrobial surfaces.

A worthwhile book to consult is *Nanotechnology Applications and Markets* by L. Gasman.[105]

Example 10.2: Cosmetics

The market for cosmetics using nanotechnology is expected to grow significantly over the coming years despite continued concern about the safety of the technology. Nanotechnology is being used increasingly in the personal care industry to develop sunscreens and antiaging formulations. The global market for cosmetics using nanotechnology was valued at $62 million as of 2007 and is forecast to grow annually by 16.6%, reaching $155.8 million by 2012, according to a BCC Research report (NANO17D). This market research company listed sunscreens as one of three applications in the biomedical, pharmaceutical, and cosmetics industries that are expected to account for 95% of the market in 2012. Nanoparticles of titanium dioxide and zinc dioxide are used in sunscreens to increase UV light absorption and make formulations transparent—ultimately making them more appealing to the consumer.

Example 10.3: Textiles

Nanotechnologies are providing incremental improvements to existing textile sectors, but they offer the highest growth in the nontraditional sectors. In the near term, the opportunity for nanotechnology in the textiles industry is in product innovation, not process innovation. Nanotechnology is more likely to be used to produce new materials or enhance the properties of existing materials than to reduce the production cost or improve quality. A number of nanotechnology innovations are already commercially available. These include:

- Stain-, wrinkle-, and liquid-resistant fabrics (see NanoTex)
- Clothing that can absorb body odors
- Clothing that emits deodorant by slow release
- Clothing that changes color with change in light
- Clothing that changes color with external or body heat

There are a number of opportunities that will be explored as nanotechnology develops further:

- New blended fabrics for specific applications (e.g., sportswear, mountainwear, military applications), including the incorporation of carbon nanotubes (CNTs) into fabrics. It is expected that composites with CNTs or interweaving with extruded CNT fibers will introduce higher conductivity as well as high strength.
- Property enhancement or alterations (UV blocking, durability, breathability, flexibility, recyclability, color retention, self-repair etc.); included in this is the introduction of electronic properties into fabrics by treatment with inherently conducting polymers. These provide capabilities such as sensing (chemical and mechanical), energy generation (photovoltaics), energy storage (batteries, supercapacitors), and charge dissipation (antistatic).
- In addition, controlled-release polymers may replenish and/or trigger release of antifungal, surface finish, or medical growth aids to the polymer surface. The triggered release systems may be made to be responsive to stimuli such as changes in temperature, humidity pH, and/or dissolved oxygen.
- Development of specific aesthetic properties (e.g., glow in the dark, color change with angle of light, color change with applied electric field).

The global market for nanotechnology in the textiles industry was around $480 million in 2007. The forecast is that nanobased products and processes will be worth $4.9 billion to the textiles industry by 2015. It is estimated that 24.6% of all textiles products available in 2015 will incorporate some form of nanotechnology, with the greatest level of penetration in the hygiene area, which covers numerous markets from household care to leisure and consumer goods to health care. Nanotechnology-based applications such self-cleaning textiles as will start to make a major impact in 2011. There will likely be a significant revenue growth in nanotechnology products in the sector from 2011 onward.

Questions

10.1: Suggest an array of sensors that could be used for an electronic tongue (5 tastes).

10.2: Why do you think that chemical microsensors have not enjoyed the same commercial success as physical microsensors? How might these deficiencies be overcome in the future?

10.3: Instrumentation miniaturization is a fast developing field. The Agilent 2100 Bioanalyzer fabricated by Agilent & Caliper Technologies Co. has been awarded the Pittcon Editors' Gold Award for 2000. How does this instrument benefit from miniaturization? What are its drawbacks? In miniaturized GC, MS, and IMS, what components have been micromachined?

10.4: At Pittcon 2000, Cyrano showcased a portable electronic nose, the Cyranose 320, which distinguishes odors using an array of 32 sensors. Each sensor is made of a composite of conductive carbon black and a non-conductive polymer. Describe how the sensors work and explain how one "trains" an electronic nose to qualitatively and quantitatively analyze unknown samples.

10.5: *Nanotechnology* is currently the buzzword in the scientific community. What does the term mean to you? Provide examples of nanoscale building blocks. What are the characterization tools (metrology) appropriate for this technology? What strategy would you consider for assembling a nanodevice and why?

10.6: Over the last five years mechanical MEMS applications saw a major change in market acceptance. In what applications and why did this occur?

10.7: The United States seems ahead in lithography-based MEMS and NEMS but is perhaps behind in non-lithography-based MEMS. Explain.

10.8: What are the three market components of NEMS today? How do they compare in size?

10.9: What are the largest MEMS applications in the automotive industry?

10.10: What was behind the infamous optical MEMS bubble bust?

10.11: Explain the concept behind the 1st level packaged MEMS and smallest commercialized unit.

10.12: How does the MEMS market compare in size to the IC market?

10.13: What is the difference between an angular rate sensor, a gyro, and an accelerometer?

10.14: Compare manufacturing options for Si-based pressure sensors and accelerometers. Give pros and cons.

10.15: Give a list of reasons why the ISFET did not become a commercial success.

mask-to-model approach, 346
mechanical drafting tools, 347
MEMCAD architecture, 348, 349
NiTi-based valve, 3D visualization, 342, 343
process simulators, 347
SUGAR V3.1, 348
Confocal laser scanning microscopy (CLSM), 298
Confocal microscopy, 297–298
Continuous manufacturing
in-line lithography equipment, 12
printed electronics engineering, 12–13
printed products on flexible substrates, 11, 12
printing industry, 11
roll-to-roll manufacturing, 11, 12
Cooper pairs, 454
Cyborg beetle system, 493–494

D

Darwin's theory, 75
Dew point sensor, 419–420
Diamond
amorphous, 252
film synthesis
CVD, 250, 251
lithographic patterning, 252
selective deposition, 252
p-i-p structure fabrication process, 252
vs. semiconductors, properties, 250
surface micromachining, 251
wide bandgap semiconductor material, 249
Diamond-based MEMS, 252
Dielectric induction, 421–422
Dielectrophoresis, 226
Differential scaling, 363
Digital mirror device, 215
Dimensional homogeneity theorem, 365
Dimensional metrology
atomic force microscopy (AFM), 317–320
confocal microscopy, 297–298
ellipsometry (*see* Ellipsometry)
fluorescence microscopy, 296–297
interferometry (*see* Interferometry)
light microscopy, 289–296
NSOM/SNOM, 310–313
scanning electron microscopy, 304–309
scanning proximal microscopes, 309–310
scanning tunneling microscope (STM), 313–317
scatterometry, 287, 289
two-photon microscopy, 298–299
Disk method, 333–334
DNA
building blocks, 61
chips
DNA arrays, applications, 108–109
sequencing and hybridization, 108
double-stranded, 62–63
hybridization, 63
replication process, 64–65
Watson-Crick pairing, 63–64
DNA arrays
applications of, 108–109
molecular diagnostics, 580–581
DNA-mediated self-assembly, 229–230
Dog-bone method, 334–337
Instron sample, 335
micro-Instron specimen fabrication, 335–336
micromachined test structure, ultimate strain, 334, 335
Young's modulus measurements, 334, 335
Dual inline package (DIP), 193–194
Dye-sensitized Grätzel design, 502–503

E

EDAX, *see* Energy dispersive analysis of X-rays (EDAX)

Electrical connection methods
flip-chip bonding, 198–200
tape automated bonding (TAB), 198
wire bonding, 197–198
Electrochemical actuators, 461–462
Electrochemical double-layer (ECDL) capacitors, 481
Electrochemical machining (ECM), 22
Electrochemical sensors
blood electrolyte and blood gas sensors, 577–578
gas sensor, 600–601
tabletop and handheld in vitro diagnostics, 576–577
Electrochemistry, fractals
2D *vs.* 3D scaling, 511
fractal electrode, 510
miniaturization, 508
networks, 509–510
scaling of, cube and sheet, 508–509
Electronic noses, 598–600
Electronic tongue, 600
Electro-osmosis, 32–33, 226
Electrophoresis, 226
Electrorheological fluids, 429–430
Electrostatic actuators
dynamics of, 395–397
electrical and mechanical circuits, 395
merits, 398–400
parallel plate capacitor (*see* Parallel plate capacitors)
performance and modeling, 400–402
Electrostatic force microscopy (EFM), 321
Electrostatic resonators
fundamental frequency, 397
quality factor, 398

Electrostatics
continuum theory, breakdown of, 380–381
scaling laws
breakdown voltage, 379
isometric scaling, 378
mean free path, 380
parallel plate capacitor, 379
Paschen curve, 380
stored energy, 380
Electrostriction
ceramic piezoelectrostrictor, ultrasonic motor, 423
mechanical deformations, 422
progressive wave, 423
Ellipsometry
ellipsometer setup, 301, 302
noncontact optical technique, 301
polarization change, 301
theory, 302–304
Energy dispersive analysis of X-rays (EDAX), 329
Energy harvesting
vs. batteries, fuel cells, and nuclear power, 505–506
energy sources, 505
vibrational types, 505–506
Environmental SEM (ESEM), 309
Eukaryotes, 57, 83–84
Everhart-Thorny (E-T) detector, 308
Exons, 70
External-combustion engines, 494
Extremophiles, 59, 60, 110–111

F

Fast microfluidic CD prototyping process
poly-dimethylsiloxane (PDMS), 275–276
PSA layers, 274–275
Ferrofluids
advantages and disadvantages, ferrowax, 447–448
coercivity *vs.* particle size, 444
ferrowax plug, 448
fractals, 446
hysteresis loop, 444
magnetic force, 445
normal-field instability, 445–446
positioning systems, multiaxle movement, 445–446
wax valves, 447
Fiber optic gyroscope, 566
Film bulk acoustic resonator (FBAR), 408
Finite element analysis
boundary and loading conditions, 345
data correlation and design optimization, 346
geometry development, 343–344
material property assignment, 344
mesh generation, 344–345
run analysis, 345
von Mises stress plot, 345–346
Flexural plate wave (FPW) devices, 409–410
bimorph and stack actuator, 410
construction and operation, 409–410
Lamb waves, 409
vs. SAW, 410
Flip-chip bonding method, 198–200
Flow cytometry, 582–583
Fluorescence microscopy, 296–297
Fractals, 364–365
C-MEMS, 511–512
definition, 506
dissipative structure, 508
in electrochemistry, 508–511
Hausdorff dimension, 507
in nature, 508
Front-end and back-end processes, 189–191
Fuel cells
microfuel cells (*see* Microfuel cells)
schematic representation, 482
stationary products, 483
type of, 482
Fullerenes, 159–160

G

Gas chromatography
advantages, 602
functional block diagram, 601
Hewlett-Packard hand held, 602
integrated, 602
mass spectrometry system, 603–604
vapor separation, 601–602
Gas phase synthesis, nanotechnology
liquid and vapor precursors, 158–159
solid-state precursors, 157–158
Genetically engineered proteins, 103–104
Genetic code
codon, 69
death and aging, 77–78
DNA and RNA, 69
evolution, 74–75
exons, 70
gene copying errors, 72
genes and chromosomes, 72–74
golgi apparatus, 71
human genome project, 76–77
introns, 70
protein-building process, 69
retroviruses, 71–72
ribozymes, 70–71
transcription, 69
transport RNA, 71
transposomes, 75–76
GIXRD, *see* Gracing incidence X-ray diffraction (GIXRD)
Glucose sensors
amperometric, 579
diabetes mellitus, 579
GlucoWatch® biographer, 32, 33, 580
manufacturing techniques, 579
MEMS microneedles, 580
Gracing incidence X-ray diffraction (GIXRD), 329

H

Hard superconductors, 451
Heat engines, MEMS
digital propulsion, 496
external and internal, 494
gas turbine, 495
megapixel microthruster array, 496
silicon/glass thruster structure, 495
in solar cells, 501–502
High-critical-temperature superconductors (HTS), 451
Hot-point probe operation, 323, 324
Human genome project, 76–77
Humidity sensor, 419–420
Hybridization, 63, 108
Hydrogenated amorphous silicon (a-Si:H)
active semiconductor device fabrication, 262
optoelectronic parameters, 263, 264
plasma-enhanced chemical vapour deposition (PECVD), 263
Hydrogen storage, 485–487
Hydrophobic and hydrophilic forces
amphiphilic molecules, 96
bicontinuous surface, 98–99
definition, 96
Gibbs free energy, 97
hydrocarbon groups, 96–97
hydrophobic effect, 97
micelle, 97–98

I

Industrial automation
electrochemical and optochemical gas sensors, 600–601
electronic noses and tongues, 598–600
gas chromatography, 601–603
ISFET technology, 601
mass spectrometry, 603–604
micromachine analytical instruments, 597
Nexus III report, 596
optical absorption instruments, 604–605
solid-state gas sensors, 597–598
Ink-jet heads, 606–607
In situ fabrication, nanoparticles
liquid phase synthesis, 154–157
lithography techniques, 146–147
self-organized epitaxial growth (*see* Self-organized epitaxial growth, nanotechnology)
solid-state processes, 153–154

In situ stress-measuring techniques, thin films
biaxial measurements, 333–334
local, intrinsic and residual stress, 333
substrate bending principle, 333
uniaxial measurements, 334–337
Instron sample, 335
Integrated sample preparation
DNA analysis devices, 592, 593
OrbiPrep system, 594–596
Tecan Boston prototype, 592–594
Interferometry
definition, 299
laser Doppler vibrometer, 323–324
Michelson interferometer, 299–300
noncontact profilometry, 299
stroboscopic LED, 323–324
SWLI, 299, 300
Internal-combustion engines, 494
Introns, 70
In vitro diagnostics, 575–576
In vivo MEMS biosensor
glucose sensing, 586–587
pH and blood gases, 586
Ion mobility spectrometer (IMS)
fabrication, microvolcanoes, 383
field ionization (FI) technique, 382
micromachined volcanoes, 382
microvolcano ionization sources, 382–383
Ni ionization source, 381
Ion-sensitive field-effect transistors (ISFETs), 601
Iontophoresis, 32–33
Isometric scaling, 357
IT peripherals and telecommunications markets, MEMS in
accelerometers, 610–611
definition, 605
ink-jet heads, 606–607
MEMS foundries, 613
MEMS microdisplays, 607–608
optical switches, 608–610
read-write heads, 606
RF-MEMS, 611–613

J

Johnson & Johnson blister pouch HIV test, 30–31

L

Lab-on-a-Chip, 539–540
Laser Doppler vibrometer, 324
Layer bonding, MEMS
alignment, 210–212
field-assisted thermal bonding, 201–204
imaging and bond strength, package hermeticity tests, 212–214
organic layers, 208–209
plastic-plastic bonding, 209–210
silicon fusion bonding, 204–207
thermal bonding, intermediate layers, 207–208
Light microscopy
airy patterns, 294
divisions, 294–295
history, 289, 292, 293
Nomarski microscope, 295
oil immersion microscopy, 294
optical microscopy, 289, 295, 296
phase-contrast microscopy, 295
resolution, 293–294
uses, 293
Liposomes, 99–100
Liquid-junction solar cell, 502–503
Liquid phase synthesis
acoustic cavitation process, 156
apparatus, quantum dots, 155
colloidal processing, 154
microemulsion nanoparticle, 156
nanoparticle formation, solution, 155
Lithographic diamond patterning, 252
Lithography-based MEMS
all-optical switching, 530–531
definition, 529
digital micromirror devices, 532
high-throughput screening, 531
mechanical and MOEMS devices, 532–533
MEMS market, 529–530
microfluidic application, 531–532
security applications, 533
Low-critical-temperature superconductor (LTS), 450
Low-pressure chemical vapor deposition (LPCVD) silicon nitride
etch characteristics, 261, 262
vs. PECVD, properties, 260, 261
Lysing
mechanical methods, 590
nonmechanical methods, 590–592

M

Magnetic actuators
bead array counter (BARC), 436–437
capacitive motor, 430
vs. electrostatic actuation, 437–438
force, translational motion, 432
levitation valve, 433–434

Serial microassembly
AC electrokinetic effect, 226
bioparticles, 226
manipulation methods, 221, 224
optical tweezers, 224–225
single-beam gradient trap, 225
Shape memory alloy (SMA) actuators, 457–459

Silicon carbide (SiC)
films, 253
poly-SiC resonator fabrication process, 253
polytypes, 252–253
Silicon MEMS (Si-MEMS) resonators
high Q argument, 245
integration argument, 245
low cost argument, 244–245
low power consumption, 245
MEMS oscillator analysis, silicon *vs.* quartz, 244
multifrequency argument, 245
size argument, 244
Silicon nitride (Si_xN_y)
applications, 259
LPCVD nitride
etch characteristics, 261, 262
vs. PECVD, properties, 260, 261
PECVD nitride
advantage, 260
vs. LPCVD, properties, 260, 261
process conditions, 260, 261
uses, 259
Single-device packaging
chip scale packaging (CSP), 193–194
dual inline package (DIP), 193–194
leadframes, metal sheets, 192–193
methods, 195
pin grid arrays (PGAs), 193–194
quad flat pack (QFP), 192–193
stress release bellows, 195
TO-5 packaged accelerometer, 194
Single-stranded RNA, 62
Smart materials, 391
Soft superconductor, 450
Solar cells
bandgaps and efficiencies, 499–500
development, 497
energy diagram, 497–498
MEMS and NEMS, 501–504
multijunction, 498
photovoltaic (PV) effect, 496
polymer, 500
quantum efficiency, 497
research efficiencies, 500
silicon-based types, efficiency, 499
Solid-state gas sensors
arrays, electronic noses and tongues, 598–600
market, 597
MGS1100 carbon monoxide sensor, 598
operating principle, 597
Taguchi gas sensor, 597–598
thin-film micromachined gas sensors, 598
Solid-state processes, nanotechnology, 153–154
Steam reforming, 483
Stem cells
bioethics, 82–83
cell-reprogramming, 81–82
characteristics, 82
types, 81
Structural metrology
stylus profilometry, 324–325
transmission electron microscopy
bright-field (BF) mode, 326
dark-field imaging mode, 326
development, 325
diffraction mode, 326–327
electron path, thin specimen, 326
vs. slide projector, 326
spot location, Bragg's law, 327, 328
spot location, Bragg's law, 327, 328
Stylus profilometry, 324–325
Supercapacitors, 481
Superconductivity
ceramic materials, 451–452
critical temperature, 451
definition, 449
Dutch physicist, Heike Kammerlingh-Onnes, 449
lanthanium-barium-copper oxide, 450–451
LTS *vs.* HTS, 451–452
magnetic levitation, 452
Meissner effect, 450
mercury, 449–450
metal superconductors, 450–451
model (*see* BCS model)

Surface acoustic waves (SAW) devices, 408–409
Surface mount technology (SMT), 193
Surface plasmon sensor
immunosensor, 584
measurements with, 584
Spreeta™, 584–585
surface plasmon resonance, 583
Surface swimmers, scaling, 371–374
Surface tension and adhesion, 374–376
Suspended membrane methods, 337–338
Suspension accelerometers, 561–563
SWLI, *see* Scanning white light interferometry (SWLI)

T

Taguchi-type sensor, 598
Tape automated bonding (TAB) method, 198
Telomeres, 77–78
Thermal actuators
parallel beam thermomechanical actuator, 455
scaling of, 456
types of (*see* Thermomechanical actuators)
Thermoelectricity, 425–428
Thermomechanical actuators
bimetallic, 456–457
shape memory alloy (SMA), 457–459
thermopneumatic, 456
Thermopneumatic actuators, 456
Thin-film batteries, 479
Thin films
conductivity and carrier type
four-point probe measurement arrangement, 323
hot-point probe operation, 323, 324
material resistors, 322
semiconductor resistors, 322
sheet resistance, 322–323
in situ stress-measuring techniques
disk method, 333–334
dog-bone method, 334–337
Poisson ratio, 338
suspended membrane methods, 337–338
stress nonuniformity measurement
cantilever beams, 340–341
cantilever spirals, 341, 342
surface micromachined structures
clamped-clamped beams, 338
lateral resonators, 340
ring crossbar structures, 338
vernier gauges, 338–340
Thin-*vs.* thick-film technology, 19
Tire pressure monitoring systems (TPMS), 555–556
TO-5 packaged accelerometer, 194
Transparent ceramic nanoparticles, 143–144
Transposomes, 75–76
Two-photon microscopy, 298–299
Type II superconductors, 451
Type I superconductor, 450

U

Ultracapacitors, 481
Universal genetic code, 113

V

Vacuum gripper, 223–224
Vacuum pressure reservoir, 33–34
Vibrating ring gyroscope, 570–571

W

Watson-Crick DNA base pairing, 63
Wire bonding method, 197–198

Frequently used constants

Quantity	Symbol	Value	Unit	Relative std. uncert. u_r
speed of light in vacuum	c, c_0	299 792 458	m s^{-1}	(exact)
magnetic constant	μ_0	$4\pi \times 10^{-7}$	N A^{-2}	
		$= 12.566\,370\,614\ldots \times 10^{-7}$	N A^{-2}	(exact)
electric constant $1/\mu_0 c^2$	ϵ_0	$8.854\,187\,817\ldots \times 10^{-12}$	F m^{-1}	(exact)
Newtonian constant of gravitation	G	$6.67428(67) \times 10^{-11}$	m^3 kg^{-1} s^{-2}	1.0×10^{-4}
Planck constant $h/2\pi$	h	$6.626\,068\,96(33) \times 10^{-34}$	J s	5.0×10^{-8}
	$\hbar$	$1.054\,571\,628(53) \times 10^{-34}$	J s	5.0×10^{-8}
elementary charge	ϵ	$1.602\,176\,487(40) \times 10^{-19}$	C	2.5×10^{-8}
magnetic flux quantum $h/2e$	Φ_0	$2.067\,833\,667(52) \times 10^{-15}$	Wb	2.5×10^{-8}
conductance quantum $2e^2/h$	G_0	$7.748\,091\,7004(53) \times 10^{-5}$	S	6.8×10^{-10}
electron mass	m_e	$9.109\,382\,15(45) \times 10^{-31}$	kg	5.0×10^{-8}
proton mass	m_p	$1.672\,621\,637(83) \times 10^{-27}$	kg	5.0×10^{-8}
proton-electron mass ratio	m_p/m_e	1836.152 672 47(80)		4.3×10^{-10}
fine-structure constant $e^2/4\pi\epsilon_0\hbar c$	α	$7.297\,352\,5376(50) \times 10^{-3}$		6.8×10^{-10}
inverse fine-structure constant	α^{-1}	137.035 999 679(94)		6.8×10^{-10}
Rydberg constant $\alpha^2 m_e c/2h$	R_∞	10 973 731.568 527(73)	m^{-1}	6.6×10^{-12}
Avogadro constant	N_A, L	$6.022\,141\,79(30) \times 10^{23}$	mol^{-1}	5.0×10^{-8}
Faraday constant $N_A e$	F	96 485.3399(24)	C mol^{-1}	2.5×10^{-8}
molar gas constant	R	8.314 472(15)	J mol^{-1} K^{-1}	1.7×10^{-6}
Boltzmann constant R/N_A	k	$1.380\,6504(24) \times 10^{-23}$	J K^{-1}	1.7×10^{-6}
Stefan-Boltzmann constant $(\pi^2/60)k^4/\hbar^3 c^2$	σ	$5.670\,400(40) \times 10^{-8}$	W m^{-2} K^{-4}	7.0×10^{-6}
Non-SI units accepted for use with the SI				
electron volt: (e/C) J	eV	$1.602\,176\,487(40) \times 10^{-19}$	J	2.5×10^{-8}
(unified) atomic mass unit				
$1\,\mathrm{u} = m_u = \frac{1}{12} m(^{12}\mathrm{C})$	u	$1.660\,538\,782(83) \times 10^{-27}$	kg	5.0×10^{-8}
$= 10^{-3}$ kg mol^{-1}/N$_A$
